

# A COMPREHENSIVE KINETICS MODEL FOR CO OXIDATION DURING CHAR COMBUSTION

Greg Haussmann and Charles Kruger

Department of Mechanical Engineering  
Stanford University, Stanford, CA 94305

## INTRODUCTION:

The most important parameter in representing energy feedback to a particle during char combustion concerns the oxidation of CO to CO<sub>2</sub>. If substantial oxidation of CO occurs near a particle, then the greater heat of combustion for the complete oxidation of carbon to CO<sub>2</sub> (94.1 kcal/mole vs. 26.4 kcal/mole for oxidation to CO) is available for energy feedback mechanisms. "Energy feedback" is here defined as any situation in which an individual particle receives a significant fraction of its heat of combustion directly, through the localized oxidation of emitted combustible species, i.e. CO. Conversely, if the oxidation of CO does not occur near a particle, then energy feedback will only occur indirectly, through heating of the bulk gas. The primary reaction product at the particle surface during char combustion is generally considered to be CO, and the location of the subsequent CO oxidation zone plays a very important role in determining the particle temperature. Ayling and Smith (1) performed experimental and modeling work which indicates that CO oxidation is not of major importance under the conditions they investigated, although they noted a need for improved accuracy in measuring char reactivities, as well as for better modeling of the gas phase CO oxidation kinetics. The modeling work presented in this paper attempts to develop an improved understanding of the boundary layer oxidation of CO through the use of a comprehensive set of kinetics expressions. It is hoped that the use of a fundamental set of kinetics expressions will more accurately represent the transient conditions occurring around an oxidizing char particle, when compared to the use of global kinetics expressions. The transport and energy equations are solved, generating both species and temperature profiles surrounding a single particle.

## MODEL DEVELOPMENT:

The CO oxidation model developed at Stanford currently employs a number of assumptions, which are listed in Table 1. One critical assumption used is the restriction that the only mass fluxes at the particle surface are CO and O<sub>2</sub>. The species mass transport equation used assume convective and diffusive transport only, with source terms calculated from the kinetics expressions. The gas phase reactions are modeled through the use of a subset of a set of expressions developed by Westbrook, et al (2) to study the pyrolysis and oxidation of ethylene. This subset is listed in Table 2. The success of this model in predicting the properties of a laminar ethylene flame suggests that it is also valid for the more simple fuels contained as subsets (i.e. CO).

The basic equation for mass transport in the particle boundary layer is below.

$$\underbrace{\frac{d}{dr} \left[ \frac{\rho_1}{\rho} \dot{m}_c 4\pi r^2 \right]}_{\text{Convection}} - \underbrace{\frac{d}{dr} \left[ 4\pi r^2 \rho D_1 \frac{d}{dr} (\rho_1/\rho) \right]}_{\text{Diffusion}} = \underbrace{4\pi r^2 \dot{p}_1}_{\text{Source}} \quad 1)$$

where

- $\rho_1$  = Mass fraction of species 1
- $\rho$  = Density of local gas mixture, gm/cm<sup>3</sup>
- $\dot{m}_c''$  = Carbon flux at particle surface, gm/cm<sup>2</sup>/sec
- $a$  = Particle radius, cm
- $D_1$  = Diffusion coefficient for species 1, cm<sup>2</sup>/sec
- $\dot{p}_1$  = Source term for species 1 (from kinetics), gm/cm<sup>3</sup>/sec

Equation 1 is non-dimensionalized through the use of the parameters below.

- $y = \frac{a/r}{(\rho_1/\rho)}$  Non-dimensional coordinate
- $X_1 = \frac{(\rho_1/\rho)}{(\rho_1/\rho)_\infty}$  Non-dimensional mass fraction
- $\beta_1 = (\rho_1/\rho)_\infty \rho D_1 / (a \dot{m}_c'')$  Non-dimensional diffusion coefficient
- $S_1 = a \dot{p}_1 / (y^4 \dot{m}_c'')$  Non-dimensional source term

The resulting form for the transport equation is:

$$F_1 = (\rho_1/\rho)_\infty X_1 + \beta_1 \frac{dX_1}{dy} \quad 2a)$$

$$\frac{dF_1}{dy} = -S_1 \quad 2b)$$

In equation 2a, the term  $F_1$  represents a non-dimensional flux, for species 1. The two equations above are solved, with the boundary conditions being:

$$\begin{aligned} X_1(y=1) &= 1 \\ F_1(y=1) &= 0 \text{ except for:} & F_{CO}(y=1) &= 28/12 \\ & & F_{O_2}(y=1) &= -16/12 \end{aligned}$$

For  $i = CO, CO_2, O_2, Ar, H_2O, O, H, OH, H_2$

The mass transport equations in the boundary layer are solved along with a simple form of the energy equation, which is similar to the transport equation used.

$$K_g \frac{d}{dr} r^2 \frac{dT}{dr} - C_g \dot{m}_c'' a^2 \frac{dT}{dr} = r^2 \dot{q}''' \quad 3)$$

where      Conduction      Convection      Source

$K_g$  = The average bulk thermal conductivity, erg/cm sec K

$C_g$  = The average bulk heat capacity, erg/gm K

As with the species transport equation, this equation is transformed into non-dimensional coordinates.

$$\frac{d^2 T}{dy^2} + \left[ \frac{C_g \dot{m}'' a}{K_g} \right] \frac{dT}{dy} - \left[ \frac{a^2}{K_g y^4} \right] \dot{q}'''(y) = 0 \quad (4)$$

The solution procedure utilized to solve the mass and energy transport equations is outlined in Table 3. The solution is first broken down into two components. The first part,  $x_{i,1}(y)$  represents the solution to the homogenous portion of equations 2a and 2b, i.e. with no gas phase reactions occurring ( $S_i = 0$ ). In this case the homogeneous solution takes a particularly simple analytical form.

$$x_{i,1}(y) = \frac{F_i}{(\rho_i/\rho)_\infty} + \left[ 1 - \frac{F_i}{(\rho_i/\rho)_\infty} \right] \exp\left[ \frac{-(\rho_i/\rho)_\infty y}{D_i} \right] \quad (5)$$

The complete solution is then represented as the sum of this homogeneous term and an inhomogeneous term,  $x_i'(y)$ . The boundary conditions on this inhomogeneous term now become particularly simple, being  $x_i'(y=1) = 0$ . One nice feature of this solution technique is that it allows the general character of the solution to be calculated immediately (the homogeneous solution), while the more difficult inhomogeneous portion can be dealt with separately. The inhomogeneous portion represents a very stiff equation, and a relaxation technique is applied to reach a solution. The species and energy equations are solved in series, as indicated in Table 3, and this procedure is repeated until a desired convergence criterion has been achieved.

#### MODEL RESULTS:

The input parameters required for this model, and the typical "base case" values used, are listed in Table 4. The values for the base case have been chosen to match conditions measured experimentally in the Stanford flow-tube reactor, in which the independent variation of many of the important reaction parameters is possible, in particular the bulk gas temperature, the oxygen concentration, and the particle size. For the current modeling results the input parameters have been independently varied around the single base case determined from the flow-tube reactor, without attempting to represent the interdependencies of the parameters. The base case value for the char reactivity at 1800K of 0.03 gm carbon/cm<sup>2</sup>/sec agrees very well with typical values measured for char reactivities (Smith (3)), although the free stream species concentrations in the Stanford flow-tube reactor can be significantly different than those found in typical pulverized coal combustion applications. The importance of this will be discussed later.

A typical temperature profile in the particle boundary layer is presented in Figure 1. The lower curve is the solution with no gas phase reactions, while the upper curve shows the effect of CO oxidation in the boundary layer. The case chosen is one in which the greatest effect of boundary layer CO oxidation was observed, although all cases show similar profiles. In both curves the particle temperature is substantially above the bulk gas temperature (by about 500K), with this temperature overshoot increased by about 60K when gas phase CO oxidation was included. Figure 1 indicates that one way to represent the effect of CO oxidation on the particle temperature would be to look at the increase in the particle surface temperature over that with no gas phase CO oxidation. This parameter has been calculated while parametrically varying the variables listed in Table 4, and the results are discussed below.

The dependence of the bulk gas oxygen concentration is seen in Figure 2. The dependence is a reasonably strong one, although for the conditions studied the temperature increase due to CO oxidation in the boundary layer is fairly low. Thus

the energy feedback due to CO oxidation, while not negligible, is not considered to be a dominant mechanism under these conditions. It is important to note that although the base case chosen indicates little CO oxidation in the boundary layer, the trends observed will give the relative importance of the various parameters studied.

The dependence on the bulk gas water concentration is seen in Figure 3. This parameter is important due to the limiting gas phase reaction  $\text{CO} + \text{OH} \rightarrow \text{CO}_2 + \text{H}$ . At low concentrations there is a strong dependence of the temperature increase due to CO oxidation in the boundary layer on the bulk gas water concentration, and this dependence tails off at higher concentrations. One reason that the temperature increase is relatively low for the base case considered in the current study is that the water concentrations present in the Stanford reactor are relatively low. The only source of water in the Stanford flow-tube reactor is the moisture and hydrogen present in the coal fed into the reactor, and the relatively low particle concentrations present ( $< 10$  particles/cm<sup>3</sup>) results in low water concentrations. Future work will consider conditions in which the water concentrations are at higher values, since this looks like a crucial parameter in studying gas phase CO oxidation, and many pulverized coal combustion environments involve water concentrations substantially above those seen in the Stanford flow-tube reactor.

The dependence of the temperature increase on the char reactivity is seen in Figure 4. The temperature increase is a relatively strong function of the char reactivity, but eventually becomes less important. This leveling off of the curve is the result of two competing processes. As the char reactivity is increased, the amount of CO present in the particle boundary layer increases, which increases the energy release due to CO oxidation near the particle. A competing effect with this is the resulting increase of the convective term in the heat transfer equation, which tends to reduce the feedback of energy released in the boundary layer back to the particle as the char reactivity increases. The net effect of these two processes is the leveling off of the curve seen in Figure 4.

The dependence on the particle radius is seen in Figure 5. It is important to note that the char reactivity has been held constant in this parametric run, while in reality the char reactivity is a strong function of the particle radius, and this must be taken into consideration in order to better represent the true effect of the particle radius. For a fixed reactivity, however, the temperature increase due to CO oxidation is a strong function of the particle radius, a quadratic type of dependence. This is due primarily to the increased heat transfer from a smaller particle to the surroundings, which tends to lessen the effect of boundary layer CO oxidation. The actual effect of particle size is some combination of this effect with the strong increase in the particle reactivity as the radius is decreased. These two effects result in opposing trends, so the net effect of the particle radius is not clear at this point.

The dependence on the bulk gas temperature is seen in Figure 6. Again there is an interdependence between this parameter and the char reactivity, a very strong influence which is not represented in the current modeling work. As expected, the effect of CO oxidation in the boundary layer is a very strong (exponential) function of the bulk gas temperature. A temperature increase of about 60K is seen at a bulk gas temperature of 2000K. When the accompanying effect of the char reactivity dependence on the temperature is included, an even stronger dependence of the temperature increase due to CO oxidation is expected.

## CONCLUSIONS:

For the conditions studied, the effect of CO oxidation in the boundary layer during char combustion does not appear to be of major importance. It is important to note that the model input parameters studied were designed to simulate conditions present in the Stanford flow-tube reactor, and that the importance of boundary layer CO oxidations in typical pulverized coal combustion environments has not yet been studied with this model.

The interdependencies between the model input parameters need to be modeled in order to better represent the actual processes occurring during CO oxidation. In particular, the parameters which indicates the possibility of a strong synergistic interaction are the water concentration, oxygen concentration, and/or the bulk gas temperature with the char reactivity.

The model results indicate the relative importance of the various parameters. The water concentration is considered to be a crucial parameter for two reasons. First, it has a strong influence on OH concentration in the particle boundary layer, which in turn plays a dominant role in the oxidation kinetics of CO. Secondly, many pulverized coal combustion environments are expected to have substantially higher water concentrations than that chosen for the base case condition used with this model. Other parameters which appear to be very important are the bulk gas temperature and the oxygen concentration, especially when their influence on the char reactivity is taken into account.

TABLE 3. SOLUTION PROCEDURE

SOLVE FOR A "FIRST CUT" VERSION,  $x_{i,1}(y)$

$$B_i \frac{dx_i}{dy} + (\rho_i/\rho)_\infty = F_i \quad 1)$$

with  $F_i = 0$  except  $F_{CO} = 28/12$ ,  $F_{O_2} = -16/12$

NOW WRITE THE SOLUTION AS  $x_i = x_{i,1} + x'_i$

where  $x'_i$  satisfies the equation .....

$$D_i \frac{dx'_i}{dy} + (\rho_i/\rho)_\infty = F_i(y) \quad 2)$$

with all  $x'_i(y=0) = 0$

Use  $x_i(y)$  and the current temperature profile to calculate the terms  $S_i(y)$  and  $\dot{q}'''(y)$  from the kinetics expressions.

Integrate  $S_i(y)$  to get a new  $F_i(y)$

SOLVE EQUATION 2) USING THIS  $F_i(y)$ , 4<sup>th</sup> Order Runge-Kutta Routine Used

THE SOLUTION IS THE NEW VALUE FOR  $x'_i(y)$

SOLVE THE ENERGY EQUATION, GIVEN  $\dot{q}'''(y)$  (See next page)

REPEAT UNTIL THE SYSTEM CONVERGES

TABLE 3. SOLUTION PROCEDURE (cont.)

The Energy Equation:

$$\frac{d^2 T}{dy^2} + \left[ \frac{C \dot{m}'' a}{K_g} \right] \frac{dT}{dy} - \left[ \frac{a^2}{K_g y^4} \right] \dot{q}'''(y) = 0 \quad 3)$$

Given a particle temperature, the temperature gradient at the particle surface  $\left[ \frac{dT}{dy} (y=1) \right]$  is calculated from an energy balance.

$$\frac{dT}{dy} (y=1) = \frac{am''}{K_g} (\text{factor}) - \frac{a\epsilon\sigma T_p}{K_g} + \frac{a\sigma}{K_g} T_w^4$$

where  
 factor = ergs released per gram carbon oxidized to CO  
 $\epsilon$  = emissivity of the char particle (taken as 0.9)  
 $\sigma$  = the Stefan-Boltzman radiation constant

Given these initial conditions, Equation 3 is solved with a 4<sup>th</sup> order Runge-Kutta routine, marching from  $y = 1$  to  $y = 0$ .

The calculated value  $T(y=0)$  is compared with the bulk gas temperature, and the procedure is repeated until convergence is obtained. (Shooting method).

DETERMINATION OF OVERALL KINETIC RATES AND  
OXYGEN REACTION ORDER FOR SARAN CHAR COMBUSTION

B.J. Waters, R.E. Mitchell<sup>\*</sup>, R.G. Squires and N.M. Laurendeau

Purdue University, West Lafayette, IN 47907

Introduction

Recent work by Mitchell and co-workers [1,2,3] on a novel entrained flow reactor has demonstrated the feasibility of extracting kinetic rate parameters from the simultaneous measurement of the temperature, diameter and velocity of individual coal particles. These rate parameters are obtained by solving the conservation equations for a coal particle as it burns in a laminar, coflowing gas stream. In this analysis, assumptions must be made about the devolatilization processes which occur during particle heatup. Specifically, the char density, ash composition and heat gain of the particle due to homogeneous combustion of volatiles become parameters in the reactor model that depend on the parent coal.

In this work, the entrained flow reactor is used to investigate the combustion of Saran char, a very low ash, high surface area, amorphous carbon. The highly irregular Saran char particles offer a coal analog without the complicating effects associated with devolatilization and catalytic impurities. We report overall particle burning rates, apparent rate coefficients, and the apparent reaction order with respect to oxygen.

Experimental Procedure

The combustion of Saran char particles is followed in a transparent, rectangular, entrained flow reactor which is described in detail elsewhere [4]. Briefly, the particles are entrained in a cold N<sub>2</sub> stream and are then injected along the centerline at the base of the 40 cm high reactor. Particle loadings are kept low to insure that their presence has no influence on the free-stream gas properties. A two-color pyrometer is used to measure the temperature of the burning particles at discrete heights in the reactor. As the particle traverses the focal volume of the collection optics, the radiant emission passes through two different sized slits. The first slit is wider (1000 μm) than the diameter of the largest particle and the second is narrower (45 μm) than the diameter of the smallest particle. The ratio of the intensity of the radiant emission measured in the first slit to that measured in the second slit is directly proportional to the diameter of the particle. The temperature measurements are calibrated with a tungsten strip lamp; the size measurements are calibrated by comparison with the size distribution of well-characterized Sphero carb particles. The particle temperatures measured in this work ranged from 1440 ± 20 K in 12 kPa O<sub>2</sub> to 2100 ± 150 K in 36 kPa O<sub>2</sub>. The measured particle diameters ranged from 80 to 170

$\mu\text{m}$  which corresponds well with the -100/+170 mesh (90-150  $\mu\text{m}$ ) particles used to feed the reactor. The velocity of each particle is determined by measuring the time it takes the particle to traverse the large slit. The particle velocities measured in this work ranged from 2.40 to 3.10 ( $\pm 0.05$ ) m/s depending on the gas temperature.

To reduce the influence of spurious signals, 200 to 300 particles were monitored at each height and the particles were grouped in bins approximately 10  $\mu\text{m}$  apart, based on their measured diameter. In this paper, a measured particle diameter refers to the diameter at the center of a bin containing at least 10 particles. A measured particle temperature or velocity refers to the average temperature or velocity for all of the particles in a given bin.

A hot, one-dimensional, laminar oxidizing gas environment is generated by a 5 cm x 5 cm array of 0.2 cm diameter  $\text{CH}_4/\text{H}_2/\text{O}_2/\text{N}_2$  diffusion flamelets. The total pressure in the reactor is constant and equal to 101 kPa. Post flame  $\text{O}_2$  partial pressures from 3 to 36 kPa and gas temperatures from 1400 to 1900 K are attained by careful control of the inlet gas mixture. During analysis of the experimental data, we found that Saran char had a negligible burning rate in 3 and 6 kPa  $\text{O}_2$  environments. Therefore, in the remainder of this paper, we only present data obtained at 12, 24, and 36 kPa  $\text{O}_2$ . Typical post flame partial pressures of  $\text{H}_2\text{O}$  and  $\text{CO}_2$  are 16 and 2 kPa, respectively.

Gas temperatures,  $T$ , are determined from radiation-corrected measurements using a Pt-Pt/13%Rh thermocouple. The gas velocity in the reactor can be modeled as,

$$\sqrt{\frac{v_g}{T_g}} = C_1 + 0.5 \sqrt{C_2 z T_g^{0.68}} + \frac{C_2 z T_g^{0.68}}{8 \sqrt{C_1}} \quad (1)$$

where  $z$  is the height in the reactor,  $C_1$  and  $C_2$  are constants that are fit to the data for each gas condition, and the two  $T_g^{0.68}$  terms account for the influence of  $T$  on the gas viscosity.<sup>8</sup> Eqn. (1) represents the solution of the<sup>8</sup> conservation equation governing one-dimensional flow in a square conduit, assuming that the boundary layer along each wall develops independently and that the fraction of the total mass flowing in the boundary layer is proportional to the boundary layer thickness.  $C_1$  and  $C_2$  are chosen to give the best fit between the measured particle velocities and the particle velocities calculated by solving the particle momentum balance (see Eqn. (3) below). An important implicit assumption in this analysis is that the density of the particles are approximately independent of burning time. This assumption is consistent with the results of the kinetic analysis discussed below.

The Saran char is made by heating Saran co-polymer (supplied by the Dow Chemical Company) to 1300 K in flowing  $\text{N}_2$  for three hours. The exact procedure used to manufacture the Saran char is described elsewhere [5]. Saran char contains no volatiles and approximately 0.5 wt% ash. Its apparent bulk density is 0.35 g/ml and its total surface

area is  $1260 \text{ m}^2/\text{g}$ , as determined by  $\text{CO}_2$  adsorption at 298 K analyzed using the Dubinin-Radushkevich isotherm. The only impurities detected by Proton Induced X-ray Emission Spectroscopy (PIXE) are 2300 ppm Cl, 22-30 ppm Ti, 10 ppm Fe, 7.2 ppm Cu, 1 ppm Zr, and 1 ppm Re.

### Theory

The equations used to follow the mass, velocity and temperature of a particle as it burns in the laminar flow reactor are given below:

$$v_p \frac{dm}{dz} = -\rho \pi d_p^2 \quad (2)$$

$$m v_p \frac{dv_p}{dz} = -mg - 3\pi \mu d_p (v_p - v_g) \quad (3)$$

$$\frac{-m v_p C_p}{\pi d_p^2} \frac{dT_p}{dz} + \rho H = \frac{2k(T_g - T_p)}{d_p} + \sigma \epsilon_p (T_p^4 - T_w^4) \quad (4)$$

The momentum equation (Eqn. (3)) accounts for gravitational and Stokes forces and the energy balance (Eqn. (4)) accounts for the thermal inertia of the particle, the heat of reaction, gas phase conduction, and radiation. The mass,  $m$ , of the char particle is determined from its apparent density and diameter,  $d_p$ . The particle velocity is  $v_p$  and  $\rho$  is the particle burning rate per unit external surface area. The velocity of the gas is given by  $v_g$  and  $g$  is the gravitational constant. The heat capacity of the particle,  $C_p$ , is taken to be that of graphite and the physical properties of  $\text{N}_2$ , the major component in the gas stream, are used for the free-stream gas properties. The viscosity,  $\mu$ , and thermal conductivity,  $k$ , of the gas are evaluated at the mean temperature ( $T$ ) between the gas and particle temperatures. The temperatures of the particle, the gas, and the medium to which the particle radiates are given by  $T_p$ ,  $T_g$  and  $T_w$  (500 K), respectively. The Stefan-Boltzmann constant is denoted by  $\sigma$ , and  $\epsilon_p$  denotes the particle emissivity (taken as 0.85). The heat released per gram of carbon consumed,  $H$ , is calculated assuming that CO is the primary combustion product.

The overall burning rate of the particle is described by:

$$\rho = k_d (P_g - P_s) = k_s P_s^n, \quad (5)$$

where  $P_g$  and  $P_s$  are the oxygen partial pressures in the bulk stream and at the surface of the particle, respectively,  $k_s$  and  $k_d$  are the chemical rate and diffusion coefficients, respectively, and  $n$  is the apparent oxygen reaction order. The chemical reaction rate coefficient includes contributions from intraparticle diffusion limitations and the intrinsic reactivity of the Saran particle. In the Arrhenius form,  $k_s$  is given as,

$$k_s = A \exp\left(\frac{-E}{RT_p}\right), \quad (6)$$

where A is the preexponential factor, E is the activation energy, and R is the universal gas constant. The external diffusion rate coefficient is given by:

$$k_d = \frac{2M D_c \text{ox}}{RT_m d_p}, \quad (7)$$

where M is the molecular weight of carbon and  $D_{\text{ox}}$  is the diffusion coefficient of oxygen evaluated at  $T_m$ .

The computational scheme employed to obtain the overall particle burning rate parameters, A, E, and n, is initiated by setting  $dT_p/dz$  equal to zero in Eqn. (4) and then using the measured  $d_p$  and  $T_p$  to calculate  $\rho$ . Using Eqns. (5) and (7),  $P_s$  can be calculated from  $\rho$ . The rate parameters are then obtained from Eqns. (5) and (6) by fitting  $T_p$  and  $P_s$  to the calculated rate using a linear least-squares routine. These parameter values are used as the first guess in the numerical integration of Eqns. (2), (3) and (4), where  $\rho$  is obtained from an implicit expression which is independent of  $P_s$  by rearrangement of Eqn. (5). The integration employs the measured  $T_p$  profile. The initial conditions used for the integration are  $T_p = 300$  K and  $v = 0.3$  m/s. A range of initial particle diameters (from 90  $\mu\text{m}$  to 190  $\mu\text{m}$ ) in 5  $\mu\text{m}$  intervals is used. When the integration reaches a height (z) where experimental measurements have been taken, the calculated relationship between  $dT_p/dz$  and  $d_p$  is used to find  $dT_p/dz$  for each measured particle size. This measured  $dT_p/dz$  is then used in Eqn. (4) to obtain a new  $\rho$ , from which updated values of the kinetic parameters are obtained for the next numerical integration. Successive iterations of this strategy are used to converge on the rate parameter values that best describe the behavior of the Saran particles. The quality of fit can be judged from the agreement between the calculated and measured  $T_p$  as a function of  $d_p$ . Both constant density and constant diameter burning are considered as limiting cases for effectiveness factors of approximately zero and one respectively. The particle ignition temperature is taken as 1000 K below which the particle burning rate is set equal to zero. Changing the ignition temperature from 300 K to 1100 K does not affect the results of this analysis.

### Results and Discussion

Equations (2), (3) and (4) can be solved to calculate the predicted relationship between particle temperature and size for a given gas environment. For the 12 kPa  $\text{O}_2$  environments at a peak gas temperature less than 1700 K and in all  $\text{O}_2$  environments less than 12 kPa, the measured particle temperatures can be fit by setting  $\rho$  equal to zero. This is in direct contrast to the burning characteristics of an hvb-bituminous coal observed by Mitchell and co-workers [2], which exhibited appreciable reaction rates in  $\text{O}_2$  environments as low as 3 kPa. This may be attributed to two factors: (1) the homogeneous combustion of the volatile matter (33% by weight) in the coal

increases the temperature of the resulting char and (2) the catalytic properties of the ash (21% by weight) increase the burning rate of the char.

If the measured particle temperature does not exceed the calculated zero-burning temperature by the approximate error in our temperature measurement ( $\pm 20$ -150 K), we can not calculate a statistically significant burning rate. Defining  $\chi$  as the ratio of the calculated burning rate to the diffusion-limited burning rate ( $\chi = \rho/k_d P_s$ ), we observed that the difference in particle temperature between  $\chi$ 's of 0.0 and 0.1 approximately corresponds to the error in the measured particle temperature. Therefore, no measurements which give a  $\chi$  below 0.1 are considered in the determination of the rate coefficients and oxygen reaction order. For the conditions of these experiments, values of  $\chi$  ranged from 0.1 to 0.6 which indicates that the overall burning rate has a high sensitivity to the kinetic rate.

For an  $O_2$  partial pressure of 36 kPa, 100  $\mu m$  particles are predicted to burn out at approximately 10 cm in the reactor, if constant diameter burning is assumed. This contradicts the experimental observation of particles as small as 90  $\mu m$  at 19 cm in the reactor. While a constant diameter model may be more applicable at lower  $O_2$  pressures, this model was not used in our analysis of the combustion kinetics. An analysis incorporating an effectiveness factor into the particle burning rate expression will be considered in future work.

Constant density burning gives good fits to the experimental data at bulk oxygen pressures of 12 and 24 kPa and poor fits to the 36 kPa data (see Figures 1, 2 and 3). A least squares fit of the kinetic rate parameters and oxygen reaction order to the calculated reaction rates at 12, 24 and 36 kPa gives

$$\rho = 6.3 \times 10^{-3} \exp\left(\frac{-27000}{RT}\right) P_s^{0.8} \quad (8)$$

where R is given in cal/mol K and  $P_s$  is given in Pa. An Arrhenius plot of the rate coefficient,  $k_s$ , versus  $1/T$  is presented in Figure 4. The relationship between  $(\rho/k_s)$  and  $P_s$  is depicted in Figure 5.

A possible reason for the discrepancy between the calculated and experimental rates for the 36 kPa data set is that the simple diffusion model considered here does not account for the large amount of CO which must diffuse out of the particle boundary layer at higher burning rates (Stefan flow). We do note, however, that when the 36 kPa data is analyzed alone, the calculated rates fit the data better, but the activation energy is lower (~17000 cal/mol) which is indicative of intraparticle diffusion limitations.

## Effect of $\text{CaCl}_2$ on Char Reaction Kinetics

M. A. Serageldin and W. P. Pan

Department of Chemistry and Chemical Engineering  
Michigan Technological University  
Houghton, MI 49931

### INTRODUCTION

This work describes the effect of  $\text{CaCl}_2$  on coal char reactivity; it is the third part in a series of studies related to boiler application (1,2) involving this metal-based salt. The information obtained in this work should be useful in understanding the effect of similar materials on the oxidative behavior of coal-char. The char was combusted in a thermogravimetric analyzer, TGA, under different partial pressures of oxygen (0.16 - 70% by vol.) in nitrogen and at constant temperature. The furnace temperatures (isothermal) varied between 673 and 1223 K. The sample mass and volumetric flow rate were close to 2 mg and 5 ml/s, respectively. This temperature range should cover the regions where oxidation occurs mainly by diffusion and mainly by chemical control (3,4).

### EXPERIMENTAL

#### Materials

Lignite coal from Velva Mine, North Dakota, was used in this work; its proximate and ultimate analysis is given in Table 1.

#### Char preparation

The coal was placed in a boat made of ceramic material and pyrolyzed in a Hoskin electric furnace (Hoskin Co.), which was regulated by an Omega 6000 temperature controller. The boat was made by splitting a length,  $l$ , of high purity alumina tube ( $l = 75$  mm and I.D. = 10 mm); it was positioned in the center of the furnace. A shielded Chromel Alumel thermocouple ( $d = 3$  mm) was placed approximately 5 mm above the boat to measure the sample temperature. The sample thermocouple reading (in the absence of a sample) was a few degrees lower than that of the furnace set temperature; for example, at the set temperature of 1248 K, the sample thermocouple (inside the furnace) recorded 1223 K.

Coal pyrolysis in a constant stream of nitrogen (0.425 ml/s at S.T.P.) was achieved over a number of steps (5). The sample was first purged at room temperature for 900 s (0.9 ks). The furnace was then switched on, setting the maximum temperature to 1248 K (which was reached in about 2.58 ks). It was left for one hour at the maximum temperature. The furnace was then turned off and left to cool in nitrogen for one hour, after which the remaining part of the coal sample, i.e. char, was emptied in a clean, dry container which was subsequently stored in a dessicator for later use.

#### Apparatus

The char was burned in a DuPont 951 thermogravimetric analyzer (TGA) coupled with a DuPont 990 recorder unit. Each sample (2 mg) was spread evenly on the platinum pan to avoid establishing a thermal gradient in the sample.  $\text{O}_2$  and  $\text{N}_2$  were mixed by different proportions. The total gas flow made by  $\text{O}_2$  and  $\text{N}_2$  was maintained at 5 ml/s. This provided a linear velocity of 18 mm/s. The percentage of  $\text{O}_2$  in the  $\text{O}_2/\text{N}_2$  mixture depended on the isothermal temperature: at the higher isothermal temperature (1223 K), the lower concentration (or partial pressure) of oxygen was used, i.e. 0.16% by volume, whereas a concentration of 70%  $\text{O}_2$  was used when the isothermal temperature was set to the lowest value investigated, i.e. 683 K. Such combinations were necessary to maintain the value of the time to 50% decomposition,  $t_{0.5}$ , above 1200 s, thus ensuring that the effect of temperature gradient is negligible (4). Lastly, before pushing the sample into the furnace, the latter was heated to the desired isothermal temperature

and left to equilibrate for 300 s. This procedure helped to reduce the time-lag before the sample reached the desired temperature.

## RESULTS

Information regarding the influence of  $\text{CaCl}_2$  on char reactivity, reaction mode, and kinetic parameters is presented in this section.

### Reactivity

The influence of oxygen concentrations and temperature on char reactivity is shown in Figure 1. A greater effect (on conversion) was produced as a result of increasing the temperature by a small percentage than by an equivalent increase in oxygen percentage in the gas. Treating the char with  $\text{CaCl}_2$  also increased its level of conversion, Figure 2. Considering that conversion vs. time plots for chars under different atmospheres are similar in appearance, a more satisfactory representation, in terms of reactivity, can be achieved by replotting conversion against a dimensionless time,  $t/t_{0.5}$  (6). Such a plot is given in Figure 3 and indicates that  $\text{CaCl}_2$  produces an insignificant effect below a conversion of  $\sim 0.58$  which would suggest that the mechanism of reaction is not altered within this zone. Between 0.58 conversion and up to  $\sim 0.68$  the "master curve" separated into two curves, one for char and the other for char plus  $\text{CaCl}_2$ . Above a conversion of 0.68 each of the above curves split into three curves, producing a total of six curves. Such a spread was not observed when char from demineralized coal was carbonized at around 1273 (6). However, evidence showing the effect of naturally occurring mineral matter in coal-char may be found (beyond a char conversion of 0.7) in Figure 1 of Tseng and Edgar's paper (4). It is, therefore, understandable that in the presence of additional mineral matter (i.e.  $\text{CaCl}_2$ ), as in this study, a more pronounced effect occurs. This is clearly indicated (Figure 3) by a greater shift of the catalyzed reaction to the left, i.e. towards a pore diffusion mode of reaction (Figure 4). The spread in the curves may be attributed to the effect of particle temperature rise (7).

### Reaction Mode of Control

To determine the mechanism controlling the reaction the data used to plot Figures 3 and 4 was replotted in terms of specific rate,  $dC/dt$ , and  $t_{0.5}$ , the time to 50 percent conversion. Values of  $dC/dt$  were obtained using the cubic spline interpolation technique (8) and the cubic spline smoothed technique. Figure 5 illustrates the extent of scatter when the cubic spline smoothed technique was not applied (white circles) to the data from Figure 3. This method was previously used by Tseng and Edgar (4) to compare the reactivities of different chars in the absence of catalysts. Figure 6 shows a number of curves obtained using this procedure for char combusted at several of the low temperatures investigated and different oxygen levels. A maximum occurred in all cases at around 0.25 conversion, which indicates that the control mechanism is chemical (3,4). Beyond 0.58 the curves delineating the different experimental conditions separated and were therefore clearly identifiable. From this presentation one can see that the maximum specific rate at a given temperature was somewhat increased by treatment with  $\text{CaCl}_2$ . It should be stated that when the conversion was less than 0.5, Figure 6 provided more detail than Figure 3.

Figure 4 was obtained by treating the data corresponding to the runs at high temperature ( $>1123$  K). The data for the six experiments followed very closely the film diffusion theoretical curve (dotted line). The theoretical lines in Figure 4 were calculated using the equations provided in reference 4.

### Kinetic Parameters

The order of reaction in the kinetic control regime was determined by plotting  $t_{0.5}$  against oxygen partial pressure (0.16 - 70 KPa) on log-log paper (4) and measuring the slope. Figure 8 shows such plots obtained at different temperatures for untreated char. The slope of the different lines was practically the same, suggesting that the average value of  $n$  for the char was 0.84. This figure is somewhat higher than 0.70 reported by a number of workers for lignite coal (see ref. 4). The value of  $n$  for char treated with  $\text{CaCl}_2$  was 0.73. Both values of  $n$  are valid for a limited temperature range, i.e. 683 - 723 K. In the diffusion control regime  $n$  equals

one (9). The activation energy was obtained by plotting  $t_{0.5}^*$ , against  $1/T$  on semi-log paper as is illustrated in Figure 9. The former value is defined as follows (4):

$$t_{0.5}^* = (P_{O_2}/P^*_{O_2})^n \cdot t_{0.5} \quad 1)$$

where  $t_{0.5}$  corresponds to the value at a base of reference partial pressure of oxygen,  $P_{O_2}$ . This was chosen to be 0.005 MPa in the present study. On the other hand, the values marked with an asterisk correspond to char reacted at the same temperature under other partial pressures of oxygen.  $n$  is the reaction order. Figure 9 illustrates results for both the high temperature runs (lower left of figure) and the low temperature runs (upper right of figure). Each circle shown in Figure 9 represents the average of four runs at different  $P_{O_2}$ , i.e. the points at a given temperature fall within the bounds of such circles. However, for calculating the activation energy, all the points were used. For example, all the runs shown in Figure 8 were used to calculate the activation energy,  $E$ , in the kinetic regime. This was equal to 154 KJ/mol for char and was reduced to 141 KJ/mol when the char was treated with  $CaCl_2$ . However, for the higher temperature runs where the mode of control was diffusional, the value of  $E$  for the untreated char was  $29.5 \pm 0.5$  and for the treated char was  $28.0 \pm 0.5$  KJ/mol. The fact that the difference is insignificant suggests that char combustion under such a regime is independent of the nature of the catalyst, a point made before by others (3,10). The activation energy in the chemical control regime may also be obtained using the following equation:

$$\log_e (P_{O_2}^n \cdot t_{0.5}^*) = \log_e A' + E/RT \quad 2)$$

where  $A'$  is a measure of the char reactivity (4) and can be expressed as :

$$A' = (1/AS_0) \int_0^{0.5} (S_0/S) dC \quad 3)$$

$A$  in Equation 3 is the Arrhenius pre-exponential factor;  $S_0$  is the specific surface area at time zero and  $dC$  is the fraction converted. Values of  $A'$  and  $E$  obtained using Equation 2 are shown in Table 2 and indicate that the reactivity of the treated char was significantly increased as a result of adding  $CaCl_2$ . The higher reactivity can also be deduced from Figure 10.

To evaluate the mass transfer resistance the Sherwood number of the char samples were calculated (Appendix 1) (4) for the data in the film diffusion controlled regime and summarized in Table 3. These values are significantly increased in the presence of  $CaCl_2$  and by temperature; however, they have a value less than 2 which refers to a spherical particle suspended in stagnant air. The occurrence of a lower Sherwood number was attributed by Tseng and Edgar (4) to a reduction in mass transfer efficiency by the sample pan (4). They also concluded that the mass transfer resistance around a single large particle would be lower than that around smaller particles on a pan. In the latter case the particle packing is also important.

## DISCUSSION

This work shows that  $CaCl_2$  promotes the overall decomposition of coal-char, i.e. it occurs during a shorter time, at constant temperature. This is in agreement with previous results but under temperature programming (non-isothermal) conditions (11). In this case the same level of conversion occurred at a lower temperature which indicates agreement between isothermal and non-isothermal studies.

Since changes in porosity and density prior to oxidation can influence reactivity, these were measured for char prepared from coal and that for coal mixed with  $CaCl_2$  (12). From Table 4 we can deduce that there is no significant change in density, total pore volume and porosity prior to combustion. Therefore the effectiveness of the additive in promoting char-oxygen reaction may be explained in terms of the following carbon-oxygen reactions (13,14):

In the above model the catalyst promotes the dissociation of the oxygen molecule adsorbed making it thus more reactive. In other words, dissociative adsorption is promoted (14). Such a

mechanism could account for the observed decrease in activation energy in the chemical control regime.

In the diffusion control regime E did not vary significantly, which would suggest that the above explanation is not applicable in this case. However, the fact that E was  $-28$  KJ/mol, i.e. higher than the usually accepted range of  $8 - 12$  KJ/mol (9), would suggest that it is possible that the regime is not totally film diffusion controlled, but that pore diffusion may also be important during the initial decomposition stage, Figures 7 and 9. (E for pore diffusion is around half of the intrinsic activation energy.) This reasoning could account for the observed shorter char decomposition time, which is indicated by lower values of  $t_{0.5}$ . The significance of the Sherwood numbers in Table 3 is now questionable. The results indicate that  $\text{CaCl}_2$  increases this number significantly and, therefore, under these conditions, mass transfer resistance was reduced. However, we can see that the values of the constant b for the film diffusion controlled regime was not significantly altered by  $\text{CaCl}_2$ . The theoretical value of b is 0.55 (4). The use of this form of the Sherwood number may be misleading considering that we do not have single spherical particles as assumed in the derivation by the authors (4) and considering that we have reason to believe that pore diffusion may also be involved.

### CONCLUSIONS

1.  $\text{CaCl}_2$  decreased the activation energy and increased the reactivity of coal char in the chemical control regime. It did not, however, have an important effect the diffusion control regime.
2. In the kinetic control regime the mechanism was not altered below a conversion of 0.58. However, at higher conversion the reaction was moved towards the pore diffusion regime.
3. At the higher temperatures pore diffusion may also play a role during decomposition, which explains why the activation energies obtained were higher than that for a totally film diffusion controlled regime.

# INFLUENCE OF METAL IONS AND PYROLYSIS CONDITIONS ON CARBON DIOXIDE GASIFICATION OF WOOD CHAR

William F. DeGroot and G.N. Richards

Wood Chemistry Laboratory, University of Montana, Missoula, MT 59812

## INTRODUCTION

The rate of biomass gasification is limited by the reaction rate of the thermally stable char which forms as a result of the initial pyrolytic degradation. This char also represents a large proportion of the energy content of the original biomass (1), and efficient conversion of the biomass should recover the energy value of this fraction. This can be achieved by reaction with oxygen, steam, or carbon dioxide, and the intent of this research was to investigate the effects of reaction conditions and inorganic catalysts on the gasification of wood chars. These chars also provide an excellent model for studying the gasification reactions of coal, since sample pretreatment and pyrolysis conditions can be varied to provide a wide range of chemical functionality in the resulting chars. Studying the chemical structure and reactivity of these chars can provide important insight into parallel reactions in coal and other carbonaceous materials.

Previous work in our laboratory on the gasification of biomass chars indicated that the inorganic species naturally present in wood were effective gasification catalysts (2), and that some of the natural inorganic species were exchangeable with cations of salts added to the wood in solution. We have studied this ion exchange process further and have found that the wood sample used in these studies contains approximately 8 meq/100 g of carboxylic acid groups, primarily as 4-O-methylglucuronic acid groups associated with the hemicellulose fraction of the wood (3). In this study we have added catalysts to previously acid-washed wood through ion exchange in order to incorporate a single catalytic species in a highly dispersed form and at a reproducible level. Selected samples were also treated beyond the ion exchange capacity in order to distinguish the effects of exchanged cations as opposed to adsorbed salts.

## EXPERIMENTAL

The wood sample used in this study was black cottonwood (*Populus trichocarpa*), a low-grade western hardwood. The heartwood and sapwood were separated and the sapwood was the primary sample studied. The wood was ground in a Wiley mill, and the 20/30 mesh fraction was retained for analysis.

Acid-washing ( $H^+$ -exchange) and ion exchange treatments were carried out by column percolation. The wood was degassed in a small quantity of the solution used for ion-exchange and transferred to a glass chromatography column. A 0.01 M solution of the acetate salt of the cation to be exchanged (at least a ten-fold excess) was then washed slowly through the column. The column was washed thoroughly with distilled, deionized water to remove any of the salt which was not bound by ion exchange. In order to add catalytic species beyond the exchange capacity of the wood, the wood was soaked in a 0.01 M solution of the acetate salt and then air-dried. All of the catalyst treatments were carried out using acid-washed wood in order that the treated samples contain only a single catalytic species.

The inorganic constituents of the wood samples were analyzed by inductively coupled argon plasma (ICP) emission spectroscopy, except for nickel which was analyzed by atomic absorption (AA) spectroscopy. Ash contents were determined by thermogravimetry (TG) at 550°C in air.

Chars were prepared in a tube furnace purged with flowing nitrogen. The wood sample was held in a porcelain boat which was pulled into the preheated furnace. After heating for a prescribed time the sample was pulled into a water condenser at the downstream end of the furnace tube, where it was cooled to approximately 10°C before being exposed to the air. Samples were stored in nitrogen- or argon-purged containers.

Cross polarization/magic angle spinning <sup>13</sup>C nuclear magnetic resonance spectrometry (CP/MAS <sup>13</sup>C n.m.r.) of the chars was carried out at the Colorado State University Regional N.M.R. Center.

Gasification was carried out in the gasification reactor/detector system depicted in Figure 1. The reactor consisted of a 1/8" I.D. alumina tube (99.8% alumina) heated by an external nichrome wire coil. The sample (3-10 mg) was confined within a 1.0 cm section of the tube by 1/8" O.D. 4-hole ceramic insulators, which also carried gas flows into and out of the reactor. The lower insulator contained a chromel-alumel thermocouple that extended 3-4 mm into the reactor and provided a reliable measure of the sample temperature throughout the reaction. The reactor was purged with a 30 cc/min flow of N<sub>2</sub> for inert conditions and an equivalent flow rate of CO<sub>2</sub> for gasification. Switching of gas flows and reactor temperature were under control of a data acquisition/control system.

Effluent gases from the reactor were mixed with a 10 cc/min air flow, causing the oxygen level of the air flow to be reduced by the stoichiometric quantity of oxygen required for combustion of any combustible gases formed by pyrolysis or gasification of the sample. The oxygen concentration of the combined gas streams was monitored by a 1/4" O.D. zirconium oxide oxygen sensor tube maintained at 900-950°K. This sensor was enclosed in a 1/2" O.D. quartz tube and produced an output proportional to the differential pressure of oxygen across its inner surface (flowing air reference gas) and outer surface (combined reactor and combustion air flows). The output of the oxygen sensor was converted to oxygen concentration during data acquisition according to the Nernst equation:

$$E = \frac{RT}{4F} \ln(P/P_{ref})$$

where R and F have their usual meanings, T is the detector temperature (°K) and P and P<sub>ref</sub> are the partial pressures of oxygen in the sample and reference gases, respectively.

For the purposes of this study it was assumed that all of the combustible gases produced were CO, and the removal of one molar equivalent of O<sub>2</sub> from the gas stream was therefore due to the gasification of one molar equivalent of carbon. The extent of gasification determined in this manner was consistently within 10% of the measured change in char weight.

The rate of gasification of a char (HTT 800°C) prepared from cottonwood is shown in Figure 2. The detector output can be integrated over the entire run to give the total extent of gasification, or it can be integrated above the baseline defined by the rate of pyrolytic gasification to give the extent of gasification due to reaction with CO<sub>2</sub>.

## RESULTS AND DISCUSSION

The ash contents and composition of the inorganic fraction of the samples used in this study are shown in Table 1. The heartwood of the cottonwood has a very high ash content, approximately four times higher than the sapwood taken from the same tree. The main components of the natural inorganic fraction are calcium, potassium, and magnesium; in addition to these elements the lignite sample has a high concentration of iron. All of these elements are potentially active gasification catalysts.

Table 1. Composition of cottonwood, treated cottonwood and lignite samples.

Acid-washing of the cottonwood sapwood removed most of the inorganic fraction, with the exception of a small quantity of residual calcium. When the acid-washed wood was treated by ion exchange with dilute salt solutions, the resulting samples contained 7-8 milliequivalents/100g with the exception of the  $\text{Cu}^{+2}$ -exchanged sample, which was treated at the 10 meq/100 g level. This is in agreement with the carboxyl content of 8 meq/100 g found previously for this sample, and indicates that ion exchange provides a high level of control for addition of inorganic cations to wood. The overall ash contents of the treated samples were all lower than that of the untreated sapwood. When the salt solution was dried onto the acid-washed wood without removing the free salts, the level of cation addition was 1.5-2.5 times higher than in the ion-exchanged samples.

Table 2 shows the effects of heat treatment temperature (HTT) and pyrolysis time on the char yields and reactivities of the resulting chars toward  $\text{CO}_2$  gasification at 800°C. The char yields of the wood and lignite do not vary significantly within the temperature range and pyrolysis times studied. However, it is important to notice the differences in char yields between the wood and lignite samples, especially with respect to the concentration of inorganic species in the chars. The char yields from wood suggest that the ash is concentrated by a factor of 7-10, resulting in an ash content of 4-5% in the char. Similarly, the ash content of lignite char would be concentrated to nearly 20% of the weight of the char.

Reactivities of both the wood and lignite chars decreased by a factor of approximately two as the HTT was increased from 800°C to 1000°C. The contribution of pyrolysis to the gas yields in both samples was relatively small and it did not vary significantly under the conditions shown. Lignite char reactivity decreased approximately linearly between 800° and 1000°C. The reactivity declined more sharply above 900°C in the wood sample. This may indicate that one of the natural catalytic species in wood undergoes a specific transformation above 900°C, rendering it inactive, and that the reactivity of wood char is otherwise less dependent on HTT than is that of coal char. The extent of wood char gasification is independent of time of pyrolysis between 5 and 60 minutes. The dependence of reaction rate on HTT found in this study is somewhat less than that reported by Hippo *et al.* for a raw lignite gasified in steam (4). These workers report nearly a three-fold increase in reactivity in steam at 750°C as the HTT is reduced from 900° to 800°C.

The rates shown in Table 2 for the lignite char gasification are similar to data reported previously by other workers for  $\text{CO}_2$  gasification of lignite chars prepared under similar conditions (5,6). Rates of wood char gasification indicate a substantially higher reactivity than reported previously for another lignocellulose-derived char gasified in  $\text{CO}_2$  at 900°C (7). The lignite char was nearly twice as reactive as the wood char over the temperature range studied, which is no doubt due in part to its higher ash content. The lower reactivity of the wood char is also explained in part by the CP/MAS  $^{13}\text{C}$  n.m.r. spectrum of the char prepared by 10 minutes pyrolysis at 600°C, shown in Figure 3. This spectrum contains a single peak centered at 130 ppm, corresponding to aromatic carbon. The spectrum is nearly identical to that of an anthracite coal (8), and anthracite coals have been shown to be more than ten times less reactive than lignite under gasification by  $\text{CO}_2$  (5). Wood chars prepared at higher temperatures contained insufficient hydrogen to provide for transfer of spin polarization to carbon, as required in the cross-polarization n.m.r. technique, and they did not give well-resolved spectra. However, it is clear that chars prepared above 600°C are highly aromatic and their gasification will require effective catalysis if it is to be carried out at lower temperatures. These n.m.r. data are somewhat surprising in view of earlier work on the n.m.r. spectroscopy of wood chars which showed a significant aliphatic component in chars prepared at temperatures up to 400°C (9).

The char yields and reactivities of chars (HTT 800°C) prepared from untreated cottonwood and catalyst-treated samples are shown in Table 3. The catalysts were added by ion exchange to the acid-washed sapwood as described earlier. Acid washing had a dramatic effect on the char yield, reducing it by a factor of more than two. Addition of transition metal and alkaline earth metal catalysts had little effect on the char yield, but the alkali metal catalysts restored the char yield to near the level found for the untreated wood. Acid-washing also resulted in complete loss of the cellular structure of the wood during pyrolysis. All of these effects parallel those reported previously for the effects of inorganic species on the carbonization of the cottonwood (10).

Table 3. Ash content and char yields (HTT 800°C) of untreated and ion-exchanged cottonwood samples and extents of conversion due to pyrolysis (P) and gasification (G) of cottonwood chars gasified for 30 minutes at 800°C in 90.9 kPa CO<sub>2</sub>.

Sample	Ash Content (%, d.a.f.)	Char Yield (%, d.a.f.)	Percent Conversion		
			P	G	Total
Cottonwood Heartwood Untreated	2.01	16.8	(100% in <20 min)		
Cottonwood Sapwood Untreated	0.51	14.8	2	40	42
Acid-washed	<0.02	7.1	2	<1	2

Mg <sup>+2</sup> -exchanged	0.17	9.4	3	15	18
Ca <sup>+2</sup> -exchanged	0.34	9.7	5	102	107 <sup>a</sup>
Co <sup>+2</sup> -exchanged	0.33	9.5	9	73	82
Ni <sup>+2</sup> -exchanged	0.32	8.0	3	34	37
Cu <sup>+2</sup> -exchanged	0.40	7.3	1	3	4

<sup>a</sup>Percent of conversion determined by integration of combustible gas detector signal was consistently 100-110% of weight of samples which gasified completely.

The most reactive sample was found to be the untreated cottonwood heartwood. The reactivity of this char reflects its higher ash content, and further illustrates the catalytic properties found previously for the natural inorganic fraction (2). The most effective ion-exchanged catalysts were found to be calcium and cobalt, which gave reactivities intermediate between the untreated sapwood and heartwood samples. Chars containing alkali metal catalysts were surprisingly unreactive in view of the excellent catalytic properties of these catalysts for lignite chars gasified in steam (4) and in air (11). Alkali metals are known to be lost during pyrolysis and gasification at these temperatures (12), but the char from potassium-treated wood contained 2.3% of ash by TG, suggesting that a large proportion of the catalyst was retained, at least during char formation.

The catalytic activities of the alkaline earth metals in wood gasification more closely parallel effects reported in the CO<sub>2</sub> gasification of coal char (5). The high catalytic activity of calcium suggests that it is the dominant factor controlling the reactivity of the untreated cottonwood sapwood and heartwood samples (see metals analysis in Table 1).

The transition metals are known to be active catalysts of CO<sub>2</sub> gasification, although they are often deactivated by oxidation during reaction (13). We have previously found this to be the case in the CO<sub>2</sub> gasification of wood chars (HTT 1000°) as well (2). The wide range of reactivities shown in Table 3 for the gasification of wood chars catalyzed by transition metals could, therefore,

represent the inherent activity of the catalyst or the activity of the catalyst under these specific conditions of pyrolysis and gasification. However, the high catalytic activity of the cobalt indicates the potential utility of these catalysts, and we are continuing to investigate the effects of pyrolysis and gasification conditions on catalysis of wood char gasification by cobalt.

The effects of different catalyst treatments are further illustrated by the reaction rate profiles shown in Figures 4-6. Figure 4 shows the rate of CO<sub>2</sub> gasification of char prepared from K<sup>+</sup>-exchanged wood. The rate is nearly constant throughout the reaction, suggesting that the reaction is zero order with respect to the mass of the char. The reaction does not appear to undergo the initial induction period which is often observed in gasification reactions. By contrast, Figure 5 shows that the gasification of the char containing calcium does exhibit an induction period, and the rate decays in a more nearly first order manner following the induction period. The char was completely gasified in this case. A third type of behavior is exhibited in catalysis by cobalt, as shown in Figure 6. In this case the reaction is very rapid at the outset and decays more rapidly than would be expected for a reaction which is first order with respect to the char. The rate approaches zero well before the char is depleted, indicating that the catalyst is being deactivated during reaction, and that a very high level of catalysis could be attained if this deactivation could be avoided.

We have also determined the rates of gasification of chars prepared from wood treated beyond the exchange capacity with the acetate salts of potassium, cobalt and calcium. Gasification rates of these chars are compared to those of the chars from ion-exchanged wood in Figure 7. In all three treatments the reactivity increased at least linearly with the quantity of added catalyst. This implies that the catalyst dispersion afforded by ion exchange is lost during carbonization, or that the catalyst added as the aqueous salt solution was equally well dispersed, presumably on the hydrophilic carbohydrate portions of the wood cell wall.

Loss of dispersion of ion-exchanged catalysts has been conclusively demonstrated in calcium-exchanged coals heated at 1000°C (14). Although the temperatures employed in the current study were somewhat lower, it is possible the same processes occur, and the potential advantage of the ion-exchanged catalyst is lost due to catalyst agglomeration. If this is the case, the relative effectiveness of the ion-exchanged catalyst should be enhanced by reducing the carbonization temperatures, and studies now underway should provide additional information on the nature of these processes.

The most surprising feature of Figure 7 is the dramatic increase in reactivity of chars prepared from wood treated beyond the ion exchange capacity with cobalt acetate. This sample was so reactive that the reaction rate at 800°C could not be accurately measured in our system. The two cobalt-treated chars (HTT 800°C) were therefore gasified at 600°C with similar results, as indicated by the dotted line in Figure 7. It is difficult to envision a mechanism whereby the acetate salt would be a more effective catalyst than ion-exchanged carboxylate salts. It is possible that the two forms of the catalyst decompose to different products, which could have different catalytic activities, although it is not clear at this time what these forms might be. In any case, the catalytic efficiency of the higher level of cobalt treatment is very promising. The reactivity at 600°C is much higher than that found previously for CO<sub>2</sub> gasification at 650°C of wood chars treated with even higher levels of iron and nickel salts (2), and it appears to be less subject to deactivation during gasification. Cobalt has previously been studied with respect to its effects on CO<sub>2</sub> gasification of graphite (13) and a highly carbonized cellulose char (HTT 1000°C) (15). In each case it was found to be similar in effectiveness to nickel and iron catalysts. The results reported here indicate a unique catalytic capacity for cobalt, which may also indicate unique properties of wood chars formed in the temperature range employed in this study.

### INTRODUCTION

Several successful test firings have been performed with coal-water fuels (CWF's) in industrial boilers. However, even with advances in atomization and burner design, there are still inherent limitations associated with CWF's which cause decreased combustor performance. These include:

- 1) Temperatures and heat liberation from CWF flames are lower than those of oil flames. This is due, mainly, to the high water concentrations, which must be vaporized.
- 2) Successful ignition and flame stabilization of CWF's usually require high primary air preheat temperatures and/or a pilot flame.
- 3) Ignition delay and burnout times of CWF droplets are longer than those of oil droplets. The residence time of CWF droplets in oil fired boilers is usually not sufficient for complete carbon burnout. Thus, the CWF firing rate must be reduced, resulting in a derating of the boiler.

One means of overcoming, or at least reducing, the combustion problems associated with CWF's is oxygen enrichment of the combustion air. Moderate amounts of oxygen enrichment, usually between 1-4 volume percent, have been used in industry to either boost production levels or improve combustion efficiency in pulverized coal and oil fired boilers (1). Oxygen enrichment increases the partial pressure of oxygen leading to acceleration of the combustion rate and, thus, the rate of char burnout of the CWF droplets. Correspondingly, there is a decrease in the total

amount of nitrogen in the combustion air, which reduces the volume of the air and flue gases. This in turn, causes an increased residence time of the CWF droplets because of lower gas velocities. Both increased combustion rate and longer residence time will help offset some of the derating associated with converting to CWF's. This study is aimed at determining the effect that a 2% increase in the oxygen content of the primary combustion air will have on the combustion characteristics of a CWF.

#### EXPERIMENTAL

A horizontally fired laboratory scale combustor, designed and built at Penn State to fire fuel oil, was modified to fire CWF's (2,3). Using this combustor, the effect of enriching the oxygen content of the primary air on the heat distribution in the furnace, the quantity of unburned carbon in the flyash and pollutant formation ( $\text{NO}_x$  and  $\text{SO}_2$ ) were investigated.

The CWF used was supplied by The Atlantic Research Corporation, Fredericksburg, Virginia. Analyses of the CWF and parent coal are given in Table 1. The origin of

TABLE 1

H <sub>2</sub> O	28.9	-

Higher Heating Value  $2.44 \times 10^7$  J/kg (10,500 BTU/lb)

#### PROXIMATE ANALYSIS (DRY BASIS)

VM	ASH	FIXED CARBON
30.9%	6.1%	63.0%

the parent coal is unknown but the analyses are typical of a high volatile eastern bituminous coal. The CWF has a solids loading of 70 wt% and a higher heating value of  $2.44 \times 10^7$  J/kg (10,500 BTU/lb). Thus, the CWF is typical of many of those that are currently under consideration by industry. The furnace was operated at a firing rate of 48 kW (164,000 BTU/lb). Oxygen enrichment was achieved by combining a stream of pure oxygen with the combustion air in order to increase the oxygen content to the desired 23% concentration. The oxygen/fuel ratio was varied from 95% to 115% theoretical oxygen. Centerline furnace temperatures were measured at various axial distances along the combustor using shielded thermocouples. Stack gases were continuously monitored for O<sub>2</sub>, CO<sub>2</sub>, CO, NO<sub>x</sub>, and SO<sub>2</sub>. Flyash samples were analyzed for carbon content.

Furnace preheat and CWF ignition were achieved by a methane pilot flame. It should be noted that stable CWF flames were not able to be maintained without pilot flame support. Thus, the methane pilot flame was maintained during all trials and provided approximately 25% of the total heat input to the combustor.

## RESULTS

Combustion trials were performed on the CWF with normal air and air enriched to 23% oxygen (2% oxygen enrichment). A 2% increase in oxygen content of the primary combustion air provided an 8.7% decrease in the volume of combustion air required and a 7.9% decrease in the volume of flue gases produced. Figure 1 shows higher furnace temperatures for the oxygen enriched case. There was approximately a 60 K increase at 5% excess oxygen. This increase in temperature appears to be quite constant over the length of the combustor. The amount of carbon in the flyash was reduced by about 5% at this excess oxygen level. The oxygen enriched flames also appeared visually brighter and closer to the burner (i.e. a shorter ignition delay).

Sulfur oxides are formed when sulfur in the fuel is oxidized during the combustion process. Figure 2 shows SO<sub>2</sub> emissions as a function of excess air (normalized to a 0% excess air basis and taking into account the reduced volume of flue gas in the oxygen enriched cases). It was found that SO<sub>2</sub> concentrations were

virtually independent of amount of excess air or oxygen enrichment for the fuel lean flames. However, the  $SO_2$  concentrations appear to be increased for the oxygen enriched fuel rich flame.

As is well known,  $NO_x$  is formed in two ways during combustion; that is by oxidation of atmospheric nitrogen (thermal  $NO_x$ ) and oxidation of nitrogen in the fuel (fuel  $NO_x$ ). The formation of thermal  $NO_x$  is very temperature dependent and is not considered to be a significant source of  $NO_x$  formation at temperatures below about 1770 K (4). The maximum temperature reached in the experimental combustor was about 1450 K therefore, most of the  $NO_x$  was assumed to be fuel  $NO_x$ . Figure 3 shows the variation of  $NO_x$  with percent excess air for both the normal and oxygen enriched combustion.  $NO_x$  concentrations were approximately 70 PPM higher in the fuel lean oxygen enriched flames. As the flames become more fuel rich the  $NO_x$  concentrations in the oxygen enriched flames somewhat approach the concentrations found in the ambient air flames.

#### CONCLUSIONS

Oxygen enriched combustion of a CWF was studied in a small scale (48 kW) combustor. It was found that a 2% increase in oxygen content of the combustion air produced:

- 1) Increase of about 60 K in furnace temperature.
- 2) More luminous flame with shorter ignition delay.
- 3) Approximately a 5% reduction of carbon in the flyash
- 4) No effect on  $SO_2$  formation in fuel lean flames.
- 5) Somewhat higher  $NO_x$  emissions for fuel lean flames but only slightly higher  $NO_x$  concentrations for fuel rich flames.

## Secondary Atomization of Coal-Water Fuel Droplets Resulting from Exposure to Intense Radiant Heating Environments

P.O. Box 880, Morgantown, WV 26505

### Introduction

The use of coal-water fuels (CWF) for direct firing in heat engines presents some challenges because conventional turbine combustors and diesel engines require short duration, intense combustion processes. It is generally understood that burning times required for efficient carbon utilization in these systems is a function of the fuel droplet size. For CWF droplets, the early stages of heating are critical. Under certain heating conditions, water is evaporated from a droplet leaving a relatively slow burning agglomerate of coal particles. Under other heating conditions, however, fuel droplets may boil explosively producing many small fragments having characteristically shorter combustion times. The behavior of CWF in a combustor depends on a number of factors including droplet size, the amount and size distribution of coal particle inclusions, and the primary mode and rate of droplet heating. A detailed knowledge of slurry droplet evaporation mechanisms is required, therefore, for accurate prediction of slurry droplet combustion times and for the design of CWF-fired heat engines.

The objective of this work is to determine the radiant energy flux conditions required to achieve explosive boiling of CWF droplets. Radiant heating is important because, when considering coal particle sizes typical of highly beneficiated micronized CWF (2 to 3 microns mean radius) proposed for use in heat engine applications, the black body radiation prevalent in combustion environments can penetrate into the droplet. The resulting internal heating of coal particles can result in superheating of the water within the droplet and thereby establish conditions necessary for explosive boiling.

Experimentally, conditions required to achieve explosive boiling were determined by electrostatically suspending and irradiating single CWF droplets with well characterized radiation pulses. Droplet behavior in these experiments was monitored using high-speed cinematography. The energy flux required for explosive boiling was determined at ambient temperature and pressure as a function of incident radiation intensity and CWF droplet size and composition. The results were then compared with theoretical predictions of the explosive boiling threshold for CWF droplets in high-temperature black body radiation fields. The primary question we wish to address is: do sufficient conditions exist, or can they be made to exist, to cause explosive boiling of CWF droplets ranging from 20 to 200 microns in diameter in realistic combustor configurations?

### Experimental

Single CWF droplets were isolated and held in an electrodynamic balance apparatus which was designed and fabricated based on the work of Davis and Ray (1). The balance, as illustrated in Figure 1, is a quadrupole trap consisting of two hyperboloidal endcap electrodes and a central ring electrode. When an AC voltage is applied between the ring and the two endcap electrodes the resulting field has a well defined null point at the geometric center of the balance. A charged droplet in the electric field is subject to a time averaged force directed toward the null point. The droplet is held at the null point by

applying a DC field across the endcap electrodes to counterbalance gravitational forces.

CWF droplets are delivered to the balance chamber from a CWF droplet generator developed specifically for use in these experiments. The basic device consists of a cylindrical piezoelectric transducer element with a capillary tube attached to one end and a fuel supply line attached to the other. The operating principle is the same as that used in ink-jet printers. Voltage pulses applied to the transducer cause sudden volume contractions which force fuel through the capillary orifice. The extruded fuel forms a monodisperse stream of droplets of uniform composition with the droplet size being determined by the capillary diameter and by the amplitude and duration of the voltage pulses. Details of the design and operating characteristics of the CWF droplet generator are provided elsewhere (2). Droplets are inductively charged by passing the droplet stream through an orifice in a charged plate prior to delivery into the electrodynamic balance chamber.

The droplet mass to charge ratio ( $m/q$ ) is directly proportional to the DC voltage required to bring the droplet to the null point. For CWF droplets the mass (and so  $m/q$ ) is continuously changing due to water evaporation and the balance voltage must be adjusted to hold the droplet at the null point during an experiment. To facilitate droplet position control and to provide accurate and precise measurements of changes in droplet size and mass, a microprocessor controlled, droplet imaging system (DIS) was developed. The DIS utilizes a Vidicon (video camera) detector to monitor droplet position and size. A microprocessor scans the vidicon every 17 ms and image processing techniques are employed to determine the droplet location and size. A control signal is then generated to maintain droplet position at the balance null point. Digital values corresponding to droplet cross-sectional area and balancing voltage (proportional to droplet mass) are generated at a rate of 60 Hz. The droplet size information is used to trigger the high-speed camera and to activate the pulsed radiation (laser) source. In addition, droplet diameter, mass and composition (percent coal by mass) are determined from the droplet size and balance control data. Figure 2 illustrates the capabilities of the DIS for droplet size and mass determination. The data shows the strong dependence of the droplet mass with changing droplet radius. Since droplet density increases as water evaporates from the CWF, the droplet mass dependence deviates slightly from the  $r^3$  relationship expected for a constant density droplet. The confidence interval (95 percent) for droplet size resolution with the DIS is  $\pm 3$  microns for droplets ranging in diameter from 50 to 200 microns. The confidence interval for mass resolution is  $\pm 50$  nanograms.

The CWF used in these experiments was a physically beneficiated (3 percent ash) micronized (3 micron mean particle radius) slurry having a composition of 62 percent coal by mass. During a typical experiment a water or dilute CWF (1 to 20 percent coal by mass) droplet was delivered to the balance chamber. The droplet size and weight were monitored by the DIS until a preselected size was attained. The high-speed movie camera was then activated and the laser was pulsed. A schematic of the experimental configuration is provided in Figure 3.

CWF droplets delivered to the balance chamber were on the order of 250 microns in diameter. Droplet size and composition were controlled by changing the initial coal composition in the droplet and by carefully monitoring the water evaporation. In this manner droplet sizes (50 to 200 microns in diameter) and compositions (50 to 70 percent coal by mass) of interest for combustion applications could be easily accessed.

## Results

Experiments were conducted using an eximer laser (wavelength 0.248 microns) to determine explosive boiling thresholds for water and CWF droplets at radiation pulse times of 10 nanoseconds. The test variables included droplet size and composition and radiation intensity. Single droplets of water and CWF (25 and 50 percent coal by mass) with radii of 25, 50, and 75 microns were irradiated from two sides (see Figure 3). The geometric cross section of the droplets then was twice  $\pi r^2$  and the incident radiation intensity was varied from  $2.5 \times 10^7$  W/cm<sup>2</sup> to  $5 \times 10^8$  W/cm<sup>2</sup> by defocussing the laser beam. At the most intense radiant heating conditions the beam cross section was larger than 300 microns so that in all cases the droplets were completely blanketed by the incident radiation.

The results of experiments performed on CWF droplets containing 50 percent coal by mass are presented in Figure 4. The results can best be described in the context of Figure 5. Over the range of conditions employed CWF droplet behavior varied from oscillatory distortions to violent fragmentation as the radiant intensity was increased. The onset of fragmentation occurred over a narrow range of intensities from about  $5 \times 10^7$  to  $1.5 \times 10^8$  W/cm<sup>2</sup>. Figure 5 shows high speed film records for 75 micron radius droplets containing 50 percent coal by mass. The framing rate was 5,000 frames per second. Figure 5A illustrates the oscillatory behavior observed for these droplets when irradiated at an intensity of  $2.5 \times 10^7$  W/cm<sup>2</sup>. At this radiant intensity no droplet fragmentation was observed. Lower radiation intensities resulted in no observable fragmentation or oscillation. When the radiant intensity was increased to  $5 \times 10^7$  W/cm<sup>2</sup> (Figure 5B) droplet fragmentation was observed. The first frame in sequence 5B shows the CWF droplet prior to initiation of the radiation pulse. The second frame of the sequence shows the droplet 0.2 ms later, after the laser pulse. The droplet appears to be a large prolated sphere suggesting the possible growth of vapor bubbles within the droplet. However, the time resolution available was not sufficient to conclusively show the existence of vapor bubbles. The third frame in the sequence shows the collapse of the prolated sphere and the formation of fuel "ligaments" attached to a central droplet core. This is followed by the breakup of the droplet to form three fragments. At this radiant heating intensity we consistently observed the formation of one or two small satellite fragments and a larger core droplet. After breakup, the fragments moved with a minimum velocity of 1 m/s. Figure 5C illustrates that as the radiant intensity was increased to  $1.2 \times 10^8$  W/cm<sup>2</sup> the fragmentation of the droplets was more violent resulting in the formation of many small fuel droplets having minimum velocities ranging from 0.5 to 2 m/s. At higher radiant intensities (Figure 5D), fragmentation was evident, however, droplet fragments had velocities in excess of 3 m/s and resolution of droplet fragments was poor.

Based on the different behavior evident in the high-speed film records modes of droplet behavior have been arbitrarily defined as: NF, no fragmentation of the droplets, F, fragmentation of the droplets to form a few relatively large droplet fragments, and EF, explosive fragmentation of the droplet to produce many small droplet fragments. Figure 4 summarizes the results of experiments using CWF droplets containing 50 percent coal by mass. The dashed line in the figure represents the theoretical predictions of Sitarski (3-5) for explosive boiling thresholds for CWF droplets exposed to high-temperature black body radiation. The theoretical predictions illustrated in Figure 4 have been modified to reflect the fact that the droplets were irradiated from two sides with a geometric cross section of  $2 \pi r^2$ . Figure 4 illustrates that explosive boiling thresholds decreased as droplet size was reduced. Experiments performed on droplets with 25 percent coal by mass showed a similar trend with decreasing

droplet size. Within the error of the experiment there was no observable difference between the behavior of CWF droplets as the coal loading was increased from 25 to 50 percent coal by mass. The presence of coal in the droplet did play an important role, however. Pure water droplets showed no evidence of oscillation or fragmentation at radiation fluxes of  $5 \times 10^8$  W/cm<sup>2</sup> and below. This observation is consistent with the fact that pure water is essentially transparent to radiation at 0.248 micron wavelength.

### Discussion

The theory developed by Sitarski (4) assumes that electromagnetic radiation is absorbed uniformly within the droplet causing strong superheating of the liquid at the center of the droplet where thermodynamic conditions approach those on the spinodal line. The sudden burst of vapor bubbles produced at the spinodal temperature then leads to disruption of the droplet. The experimental observations are consistent with this physical description of the explosive boiling phenomena and the agreement between the experimentally determined thresholds for explosive fragmentation are in excellent agreement with the explosive boiling thresholds predicted by Sitarski.

Two alternative mechanisms for droplet breakup were also considered. They were the effect of radiation pressure and the potential for significant ionization and plasma formation. Calculations were performed to evaluate the radiation pressure associated with the laser pulse. The momentum imparted to the droplet due to the light pressure was found to be two orders of magnitude lower than the observed momentum (determined from the velocity of the fragments). Therefore, the contribution due to radiation pressure was insignificant. At radiation intensities similar to those employed in the present study, plasma formation has been observed for aerosol particles in air (6, 7). The accompanying laser breakdown depends on a number of factors including, the radiation wavelength, intensity and pulse time and the optical properties and size of the aerosol particles. Plasma formation and growth is usually accompanied by a characteristic flash of light followed by an acoustic pressure pulse (shock wave) as the plasma cloud expands at a rate of 2 to 3 km/s. Over the range of radiant heating conditions reported in Figure 4 there were no observations supporting the formation of a plasma cloud. At radiation intensities above  $10^9$  W/cm<sup>2</sup>, however, the characteristic signs of plasma formation were evident.

### Conclusion

Capabilities have been developed to determine radiant intensities required to achieve explosive boiling (secondary atomization) of CWF droplets of well defined size and composition. The system has been used to determine explosive boiling thresholds for CWF droplets at short duration high intensity radiant heating conditions. The experimental results are both qualitatively and quantitatively in good agreement with theoretical predictions for explosive boiling thresholds. Attention has now been directed toward applying these techniques to make measurements of explosive boiling thresholds at radiation wavelengths in the infrared region of the energy spectrum with millisecond heating times to address conditions which are representative of combustion applications.

### INTRODUCTION

Bi-dimensional fluidized beds have been since long adopted for studying fundamentals of fluidization. Optical accessibility has been a valid tool for analysis of bubbles and their interaction, in spite of the existing behavioural difference between three and two dimension experiments. A bi-dimensional bed has been recently used for application of mass spectrometric analysis of gas concentration profiles in single bubbles rising through a bed kept at minimum fluidization velocity (1).

Coal combustion and gasification in fluidized bed is now actively and intensively studied. Models of coal combustion process, including volatilization have been proposed. However lack of optical access into traditional fluidized bed combustors, renders difficult the comparison between model prediction and experimental result.

The idea of developing a bi-dimensional combustor, fitted with mass spectrometric probe seemed very appealing, though of not easy design and construction.

In this paper design and construction of a bi-dimensional fluidized bed combustor (F.B.C.) and result of first experiments performed are reported.

### F.B.C. DESIGN

Very crude and preliminary calculations show that it is not possible to operate steadily a bi-dimensional fluidized bed coal combustor normally exposed to ambient. Assuming for a quartz sand bed (70-600  $\mu\text{m}$  size) a temperature of 1150-1200 K, radiant heat transfer reaches values of 80 kW/sqm, which cannot be carried by enthalpy of fluidizing gas. Generation of this substantial power is not possible by means of combustion itself, owing to the small amount of coal in the bed. Consequently it is necessary to feed the F.B.C. with extra power in order to obtain a steady operation. Hypothesis of adopting Vycor<sup>TM</sup> silica glass covered with thin tin oxide layer has been discarded, since its application at these temperatures are not known, neither it was possible to assess the semiconductivity properties at high temperature of tin oxide layer.

The obvious solution to the problem was to design a furnace, fitted with windows, in which the bed had to be enclosed. The furnace essentially consists of a parallelepipedic enclosure, the dimension of which are 1070 mm height, and 890 mmx1440 mm base. Starting from the inside, furnace walls are made of Triton Kaowall<sup>TM</sup>, which is particularly suitable for high temperature, of Calsil<sup>TM</sup>, which has good insulating properties and is asbestos free and, for the outer layer, of Monolux 500<sup>TM</sup>, which has good mechanical properties, but can stand lower temperatures. The bottom has been made of CER 21/M<sup>TM</sup> which presents good mechanical properties even at high temperature. Thickness of insulation has been calculated on the basis of following assumption: outer wall temperature <333 K, inner wall temperature equal to maximum operation temperature, linear temperature gradient through walls. Constant thermal conductivity for each material, averaged on temperature has been used in calculations. Front, rear and top walls are removable. Furnace top possesses a slot, which coincides with highest level of bed free-board and can be connected to an exhaust line. A square window, 250 mmx250 mm, made of polished Vycor<sup>TM</sup> glass as been made on front and rear panel. Windows are parallel to the bed and permit its optical observation. Four electrical resistances, each providing 3.6 kW, are immersed into a ceramic support, which is 50 mm thick, 300 mm wide and 600 mm high. These resistances give the necessary power to furnace, for every possible regime of operation, since several series and series-parallel insertions are possible. Calculations show that at steady state about 4 kW are necessary for keeping furnace at 1223 K. However resistances are

capable of producing 14.4 kW, which are useful for shortening apparatus start up.

A proportional, integral temperature controller has been designed which features a thyristor power unit, and safety set points which can be triggered by maximum and minimum temperature and which can be overridden during start up procedure. For safety reasons, thermocouple failure triggers the power off. Owing to large heat capacity of furnace and prevalent radiant heat transfer within enclosure, uniform temperature is achieved throughout the bed.

The bed is confined by means of two polished Vycor (<sup>TM</sup>) glass walls, 18 mm apart, inserted into slots created on furnace sides. The transparent walls are made of a double layer of sheets, 6 mm thick, 300 mm wide and 300 mm high. Owing to the limited size of Vycor (<sup>TM</sup>) sheets the two layers are skintled in order to prevent air and solid materials leakage during operation. Vycor (<sup>TM</sup>) glass walls continue up to the top of furnace, consequently free board is kept at the same temperature of the bed. Figure 1 shows the apparatus.

Even gas distribution at bottom of bed is achieved by means of a distributor made of aluminum silicate, which practically consists of a porous plate (140-200  $\mu\text{m}$  pore size) 20 mm thick. Great care has been taken to seal the junction between distributor and bed. To this end a special Triton Kaowall (<sup>TM</sup>) cement has been used.

Flow of fluidizing gas is measured by means of conventional rotameter. Inlet gas pressure is measured by conventional open tube manometers. Temperature of bed is measured by means of thermocouple. On each side of the bed at different heights three channels have been drilled and fitted with 12 mm alumina tubes for coal feeding and gas sampling.

Arriflex cine camera, 16 mm, at 50 frames per second has been used for optical observation and recording of F.B.C. behaviour. Analysis of single frames has been carried out by means of a graphic tablet hooked to an Apple IIe personal computer. Bubble areas were evaluated by means of specific software. Time variation of dimension of coal and char particles was also analyzed by means of the same technique.

A continuous sampling  $\text{CO}_2$  analyzer was also used for monitoring coal combustion.

The whole apparatus performed as expected. The bed could be kept steady at temperature of 1223 K as long as necessary.

## RESULTS

To the best of authors' knowledge, the bi-dimensional F.B.C. is the first that has been ever constructed. Consequently it seems that up to now no direct optical test has been made yet on general fluidodynamics behaviour of fluid beds at high temperatures. Results reported in the following refer to a bed 260 mm wide and 140 mm high of sand (density 2.6  $\text{g}/\text{cm}^3$ ). Mass of solids was kept constant at 1 kg. The first set of experiments that has been run was aimed at assessing the possibility of testing these fundamental aspects of fluidization.

Minimum fluidization velocity  $U_{mf}$  has been experimentally evaluated for sand of two different sizes: 300+400  $\mu\text{m}$  and 850+1000  $\mu\text{m}$ . In fig. 2  $U_{mf}$  values measured at experimental conditions are reported against temperature. For both sizes  $U_{mf}$  decreases with increasing temperature. Results are in accord with those obtained by Botterill and Teoman (2) and can be easily explained on the basis of viscosity increase with increasing temperature. Comparison with available theoretical models has not been fully accomplished yet, owing to the limited number of data. However first trials seem to indicate that for smaller size, available theory extrapolated at operation temperatures underestimate  $U_{mf}$ , whereas for larger size  $U_{mf}$  is nearly correctly estimated at temperatures lower than 673 K and is overestimated at higher temperatures.

Several films have been shot by means of cine camera with the aim of measuring bed expansion and bubble volume fraction at different temperatures. Results refer to bed of sand 300+400  $\mu\text{m}$  size. In fig. 3 bed voidage is reported against relative fluidization velocity  $U/U_{mf}$  for different bed temperatures. Bed voidage was evaluated by measuring on film frame bed height at different  $U/U_{mf}$ . Data show that bed voidage depends on temperature.

Experimental technique features the possibility of measuring bubble size on film frame by means of graphic tablet digitization. In fig. 4 an example of digitized frame is reported. Bubble fraction at different  $U/U_{mf}$  and temperatures have been measured by means of the above technique. Results are reported in fig. 5.

Combustion at 1123 K of batch of five particles of South African char, approximately spherical, of 130 mg mass and 6 mm diameter each, has been followed by cine camera recording and by monitoring  $CO_2$  concentration in exhaust gases. Burn-out time has been determined by observation of particle disappearance and by  $CO_2$  monitoring. Same experiment has also been performed with batch of three particles of South African coal, each of 400 mg mass and of 9 mm diameter. Data are reported in fig. 6. Cine camera was run at immission of particles into the bed and after 228 s and 552 s. In fig. 7 char particle diameter against time is reported as evaluated by the two methods. Data obtained by film frame analyses and data obtained by calculation of particle diameter reduction from  $CO_2$  concentration measurement, to compare fairly well. On the same diagram theoretical variation of char particle diameter with time has been reported. Curve is drawn assuming shrinking particle model and diffusion control.

Combustion of a batch of three South African coal particles tested also apparatus capabilities of following devolatilization. Coal particles were spherical with 9 mm diameter and with a weight of 400 mg each. Devolatilization phase could be followed at ease and flamelets generated by gas combustion were observed.

#### CONCLUSIONS

The first results confirm that the apparatus that has been developed can be a powerful tool for studying high temperature processes in fluidized beds. Specifically fundamental fluidodynamics of beds can be investigated and combustion process of coal can be followed, even during devolatilization phase. Hypotheses of current models can also be checked, though with the limitation deriving from bi-dimensionality.

### Introduction

For the last several years, Battelle Columbus Laboratories has been actively conducting research on the development of a practical, cost-effective process for improving both the fixed-bed gasification(1) and the boiler combustion(2) characteristics of high-sulfur, agglomerating, low-reactivity bituminous coal. The product of this research is a calcium-impregnated coal called Battelle Treated Coal (BTC), given the acronym BTC. The properties of BTC are much different from those of the raw coal from which it is processed(1,2). Specifically, these differences are:

- Increased ASTM volatile matter content.
- Higher char reactivity.
- Reduced tar formation tendency.
- Hotter ash fusion temperatures.
- Diminished coal particle agglomeration tendency.
- Enhanced sulfur retention by the ash.

As near-term markets for gasifier and boiler coal diminish or stabilize, respectively, Battelle has expanded the search for other old or new applications for bituminous coal that would also benefit from the alterations that could be given it by the Battelle calcium impregnation process. Recent planning studies by the United States Department of Energy (U.S. DOE) have forecast a need for coal-fired combustion turbines for the repowering of electric utilities when they become capacity-limited or deficient in the early-to-mid 1990s(3). The purpose of the program reported here is to demonstrate the promise of utilizing BTC as a fuel in advanced, coal-capable combustion turbines.

This paper is the second(4) in a series to present the results of a U.S. DOE-sponsored program designed to determine the intra-particle sulfur capture efficiency of BTC under simulated combustion turbine conditions. The BTC consisted of either of two high-sulfur (>4 percent by weight) Illinois No. 6 coals that had been impregnated with calcium-containing catalysts using a proprietary Battelle process. The simulated turbine combustion conditions consisted of super-atmospheric pressure, ultra-high excess air levels, average firing temperatures, and near-quantitative carbon conversion. Combustion test results reported here will focus on the parametric and comparative effects of raw coal organic sulfur content, calcium source, and calcium impregnation technique on sulfur capture efficiency. The effects of pressure and temperature on sulfur capture efficiency, as well as on ignition, burnout, and ash deposition, were the subjects of the earlier report(4).

## Experimental

A coal-fired combustion turbine simulator was constructed at Battelle by converting a continuous high-pressure reactor from a gasifier to a combustor(4). A schematic of the combustion turbine simulator is shown in Figure 1. This device is capable of simulating(3,4) the following combustion turbine conditions:

- Super-atmospheric pressure: 4 atmospheres.
- Maximum coal flame temperature: 2600 F.
- Maximum firing temperature: 1900-2100 F.
- Maximum liner temperature: 1000-1500 F.
- Primary fuel/air ratio: 20 percent excess air.
- Overall residence time: 150-300 milliseconds.
- Carbon conversion efficiency: 99+ percent.

A premixed methane/air pilot flame was first used to ignite the down-flowing pulverized coal feed at atmospheric pressure. The coal firing rate was then adjusted to about 40,000 Btu/hour. Primary air amounted to 20-30 percent of the total air required for combustion at 20 percent excess air. Secondary air made up the remainder. Temperatures were continuously monitored down the vertical axis of the combustor at locations in the pre-to-post flame zones using Inconel-sheathed Chromel-Alumel thermocouples. Firing temperature was adjustable over a 200 F range by either varying the amount of tertiary dilution air introduced or by oxygen enriching the secondary air to various levels. After combustion was completed within the 12-foot long, 6-inch diameter combustion chamber, samples of gaseous and solid products were collected using an uncooled stainless steel probe or a cyclone mounted in the exhaust, respectively. Flue gases were analyzed for CO<sub>2</sub>, CO, O<sub>2</sub>, and SO<sub>2</sub> using conventional analytical instrumentation(4). Once the diagnosis of atmospheric-pressure combustion conditions was completed, the system was pressurized to 65 pounds per square inch absolute (psia) and the gas/solid sampling procedure repeated.

The combustion test plan consisted of experiments designed to determine the comparative in situ sulfur capture efficiency, under simulated combustion turbine conditions of: (a) raw pulverized bituminous coal, (b) pulverized BTC prepared from this raw coal, and (c) a physical mixture of the raw pulverized coal and pulverized lime with the same amount of calcium added as for the BTC.

The two raw bituminous coals used were both from the Illinois No. 6 seam. As Table 1 shows, both had total sulfur contents of greater than 4.50 weight percent. The difference between them was that one's total sulfur was predominately organic, whereas the other's consisted of a near-equal split between organic and inorganic sulfur.

The raw coals were first dried to about 2 percent moisture, pulverized to 85-90 percent minus 200 mesh (75 microns), and then fired.

To produce BTC, coarse raw coal, 100 percent minus 20 mesh (850 microns), was first treated via the proprietary Battelle calcium impregnation process (1) to increase its molar Ca/S ratio to the levels listed in Table 1. Either commercial grade or technical grade lime was used as the source of the calcium. The difference between these calcium sources is purity and cost with the commercial grade being less pure and less expensive. The BTC was then dried to 2-3 percent moisture, pulverized to 85-90 minus 200 mesh, and then fired.

For the third fuel, finely-pulverized (85-90 percent minus 200 mesh) raw coal was physically mixed with either the commercial or the technical grade lime, each having a particle size of 100 percent minus 325 mesh (45 microns), and then fired. The physical mixtures' molar Ca/S ratios were adjusted to be as equivalent as possible to that of the BTCs (see Table 1).

#### Results

The following are the significant new results regarding sulfur capture of these latest combustion tests, the results of which are documented in Table 1:

- Inherent sulfur capture by raw Illinois No. 6 seam coal appears to be independent of sulfur form, i.e., organic vs inorganic.
- Sulfur capture by Illinois No. 6 seam coal treated via the Battelle calcium impregnation process (BTC) appears to be independent of sulfur form and grade of lime at both low and high Ca/S ratios.
- Sulfur capture by BTC made from Illinois No. 6 seam coal is at least 50 percent more efficient than that achievable upon physically mixing raw coal and either grade of lime.
- Sulfur capture by BTC at low levels of calcium impregnation exhibits a positive pressure dependence over the entire range of pressures studied.
- All other positive effects of Battelle calcium impregnation on raw coal combustion performance(4) -- higher ash fusion temperatures, lower free-swelling indices, smaller fly ash, negative pressure dependence for NO<sub>x</sub> -- are observed for the organic sulfur enriched Illinois No. 6 seam coal.

**Mechanism Of Radical-Radical Reactions:  
The Reaction Of Atomic Hydrogen With The Formyl Radical**

Lawrence B. Harding and Albert F. Wagner

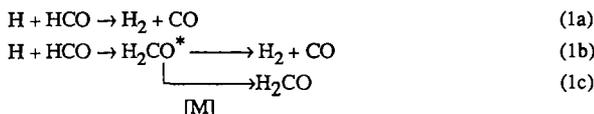

Chemistry Division, Argonne National Laboratory,  
Argonne, IL 60439

**Abstract**

The addition and abstraction reaction pathways on the potential energy surface for H+HCO have been characterized by an *ab initio* four electron, complete active space, self-consistent field electronic structure calculation. The elimination pathway to go from the excited adduct H<sub>2</sub>CO\* to products H<sub>2</sub>+CO has already been characterized by others[1]. All this information is used in variational transition state theory and RRKM calculations to calculate a rate constant as a function of temperature and pressure. The room temperature value agrees with the lowest of three experimental measurements. The results indicate that abstraction is the dominant process.

**I. Introduction**

While the dissociative dynamics of H<sub>2</sub>CO have been well studied[1,2], the reverse reactions of the dissociation products are less well known. In particular the three measurements[3-5] of the rate of H+HCO differ by almost an order of magnitude and have only been done at room temperature. Like many radical-radical reactions, H+HCO has several possible pathways to reaction:

Reactions (1a) and (1b) are disproportionations by either direct, bimolecular abstraction or addition-elimination. Reaction (1c) is recombination by pressure stabilization of buffer gas [M]. In this theoretical study, the reaction pathway of abstraction (1a) and of adduct formation in (1b) and (1c) are characterized by electronic structure calculations. Then this information along with the characterization of the elimination of (1b) are used in dynamics calculations of the rate constant.

**II. Potential Surface Calculations**

The calculations reported here employ the Dunning[6], valence, double-zeta contractions of the

\*Work performed under the auspices of the Office of Basic Energy Sciences, Division of Chemical Sciences, U. S. Department of Energy, under Contract W-31-109-Eng-38.

Huzinaga[7] (9s,5p) sets of oxygen and carbon centered primitive Gaussians. For the hydrogens the (4s/2s) contraction was used with a scale factor of 1.2. In addition sets of d polarization functions were centered on the carbon and oxygen ( $\alpha_C=0.75$ ,  $\alpha_O=0.85$ ) and one set of p polarization functions on each of the hydrogens ( $\alpha=1.0$ ).

With this basis set, four electron, four orbital complete active space, self-consistent field (CASSCF) calculations were carried out. In this wavefunction the four electrons involved in the two CH bonds of formaldehyde are correlated with all possible orbital occupations of four orbitals, a total of 20 configurations. The remaining electrons are not correlated. With the exception of minor differences in the basis set, this is the same wavefunction used by Dupuis et al[1].

The calculations were carried out with the Argonne QUEST-164[8] programs, SOINTS and UEXP. An average calculation on a planar point took approximately 11 minutes on the FPS-164 while a typical nonplanar point required 16 minutes. The energy was evaluated at a total of approximately 300 points.

Initially it was assumed that the addition and abstraction reaction coordinates could be approximated by the distance between the carbon and the incoming hydrogen. The grids of points were calculated at 0.5 au increments in this CH distance along the two paths. A total range of CH distances from 5 to 10 au was covered. Variations in the inactive geometrical parameters of 0.05 au for bond lengths, 5°-10° for bond angles and 10°-20° for the dihedral angle were used. These grids of points were then fit separately to Simons-Parr-Finlan type expansions, using the program SURVIB[9], in order to obtain local representations of the potential surface in the region of the abstraction and addition reaction paths. The dependence of the energy on the angle of approach is depicted in Figure 1. From this figure it can be seen that there are two distinct reactive channels, one corresponding to abstraction and one to addition. The calculations predict no significant barrier in either channel.

The two reaction paths were then obtained by following steepest descent paths in mass-weighted, atomic cartesian coordinates. The starting points for the two paths were obtained by freezing the CH distance at 8 au and optimizing the remaining geometrical parameters. Two minima were found in this procedure (see Figure 1), one in which the incoming hydrogen is trans to the HCO hydrogen and a second in which the two hydrogens are cis, these were used as starting points for the addition and abstraction paths respectively. A plot of the energy along the two reaction paths is given in Figure 2. Vibrational frequencies were obtained along the reaction paths by numerically calculating the second derivative matrix in mass-weighted atomic cartesian coordinates, projecting out the translations, rotations, and gradient vector, and then diagonalizing the resulting 5 dimensional matrix. Plots of the vibrational frequencies along the two reaction paths are given in Figures 3 and 4.

### III. Rate Constant Calculations

The calculated frequencies, structures and energetics as a function of distance along the reaction path can be used directly in a variational transition state theory (VTST) calculation to produce the abstraction rate constant, i.e., for Reaction (1a). In this calculation, the rate constant at each temperature is that one which is a minimum with respect to position along the reaction path. Two of

the vibrational frequencies go to free rotations of the HCO in the reactant asymptote. The partition function used in the VTST expression for these two degrees of freedom is approximated as the minimum of the vibration or free rotation partition function. Subsequent calculations will include the hindered rotor effects. The resulting abstraction rate constant is shown in Fig. 5 along with the three rate constants measurements referred to in the introduction.

The measurements include both abstraction and addition processes. The VTST rate constant for addition is also in Fig. 5. This rate constant was determined in the same way as for abstraction, only with the calculated addition frequencies, structures and energetics. However, unlike abstraction, this rate constant can not be directly compared to experiment because it is only an adduct formation rate constant to form metastable, highly vibrationally excited  $\text{H}_2\text{CO}^*$ .  $\text{H}_2\text{CO}^*$  may decay back to reactants, may go on to products by eliminating  $\text{H}_2$ , i.e., Reaction (1b), or may be stabilized by buffer gas to thermalized  $\text{H}_2\text{CO}$ , i.e., Reaction (1c). That fraction of the adduct formation rate constant that corresponds to elimination or stabilization is what is needed for comparison to experiment. To determine that fraction, characterizations of the potential energy surface in the region of the  $\text{H}_2\text{CO}$  equilibrium and the elimination transition state  $\text{H}\cdots\text{H}\cdots\text{CO}$  are required. Then the stabilization rate constant and variational RRKM theory can be used to calculate the rate constant for Reactions (1b) and (1c).

In electronic structure calculations of comparable quality, Dupuis et al.[1] characterized the structure and frequencies of both  $\text{H}_2\text{CO}$  at equilibrium and the  $\text{H}\cdots\text{H}\cdots\text{CO}$  elimination transition state. The calculated properties at the equilibrium are very close to the experimental values and for consistency are used in the rate constant calculations. In a careful study of the energetics, the best estimate of the calculated barrier height to elimination is  $81\pm 3$  kcal/mole with the zero point energy correction. Experimental values[2] for the energetics give a number of about  $84\pm 1$  kcal/mole. The experimental value for the energetics of  $\text{H}_2\text{CO}$  dissociation to  $\text{H}+\text{HCO}$  is about  $86\pm 2$  kcal/mole and is due to thermochemical measurements with the uncertainty from the heat of formation of HCO[10]. These experimental values for the energetic placement of asymptotes and barrier heights will be used in the rate constant calculations.

With the transition states selected at each temperature by the VTST calculation for formation of the adduct, chemically activated RRKM calculations were performed to determine the subsequent fate of the adduct. These calculations are of a standard form[11] with total angular momentum approximately included only as a thermally averaged value. A direct count Beyer-Swinehart algorithm[12] is used. Tunneling through the elimination barrier is included in an Eckhart manner[13]. The final pressure dependent rate constant produced is in the high pressure limit the adduct formation rate constant in Fig. 5.

The calculations require as input the rate constant for stabilization of the  $\text{H}_2\text{CO}^*$  by buffer gas. In the three experiments, the buffer gas differs. CO,  $\text{H}_2\text{CO}$ , and Ar were used at pressures ranging from a few torr to atmospheric. Under these conditions, stabilization of the adduct turns out to be an unlikely event and the calculations are not particularly sensitive to detailed specifications of the stabilization rate constant. The rate constant used is the the Lennard-Jones gas kinetic rate constant

times an efficiency factor for stabilization. The Lennard-Jones parameters are taken from the tabulation of Ref. 14 with the values for ethylene used for  $\text{H}_2\text{CO}^*$ . The efficiency factor is determined in a way to empirically mimic a master equation solution[15] and requires as input the average energy  $\langle\Delta E\rangle$  transferred between buffer gas and metastable adduct per up and down collision. This value used ( $-20\text{ cm}^{-1}$ ) were those measured[16] for  $\text{CS}_2$ , the only triatomic where direct measurement of  $\langle\Delta E\rangle$  have been published.  $\langle\Delta E\rangle$  was presumed to be independent of temperature[17].

To complete the input for the chemically activated RRKM calculations, the external rotations of the equilibrium and saddle points must be classified as either active or adiabatic. The external rotations are presumed similar to those of a symmetric top. The conserved total angular momentum and its projection on a space fixed axis are associated with the two larger moments of inertia and are treated adiabatically. The projection of the total angular momentum on the molecular axis is associated with the smallest moment of inertia and is not necessarily a conserved quantity. If there is substantial vibration-rotation interaction through centrifugal stretching or Coriolis coupling, the energy associated with this projection becomes active[18]. The amount of vibration-rotation interaction in  $\text{H}+\text{HCO}$  is unknown and so in the calculations this degree of freedom was treated both ways, either actively or adiabatically. Fortunately the results are not particularly sensitive to the choice and only those for the active treatment will be discussed.

In Fig. 5 the final calculated rate constant for reactions (1b) and (1c) as a function of pressure in Ar buffer gas is displayed for two different choices of the energetics of dissociation of formaldehyde. As mentioned above the experimental uncertainties in both the height of the elimination barrier and the  $\text{H}+\text{HCO}$  asymptote relative to the bottom of the  $\text{H}_2\text{CO}$  well are a few kcal/mole. The two cases in Fig. 5 are for the difference between the asymptote and barrier (i.e.,  $\Delta E$ ) being as large or as small as these uncertainties allow. The pressure dependence of the calculated rate constants show that stabilization (1c) is a minor process relative to elimination (1b) although, as expected, it is more important if the elimination barrier and the  $\text{H}+\text{HCO}$  asymptote are very close to one another. The importance of elimination should increase with changing the buffer gas to CO or  $\text{H}_2\text{CO}$  but not so as to qualitatively change the results. The figure also shows by comparison to the adduct formation rate that the most likely fate of the adduct is to decompose back to reactants. This is due to the fact that the elimination transition state is a tight, constricted configuration and the lifetime of the adduct (which controls stabilization) is short because it is only a 4 atom system. As a result, direct abstraction is the dominant process. The sum of abstraction, addition-elimination, and stabilization rate constants gives a total rate constant at or slightly below (depending on the choice of energetics) the lowest and most recent experimental value[5].

Abstract

We use *ab initio* potential energy surfaces, including new parametrizations of the bending potentials for the two lowest electronic states, to calculate the rate constants for the reaction  $O(3P) + H_2$ . The dynamics calculations are based on variational transition state theory with multidimensional semiclassical tunneling corrections. We present results for the temperature range 250-2400K. In general the calculated rate constants for the thermal reaction are in excellent agreement with available experiments. We also calculate the enhancement effect for exciting  $H_2$  to the first excited vibrational state. For the reaction of vibrationally excited  $H_2$  the rate constant is based on a dynamical bottleneck of 7.2 kcal/mol, as compared to a saddle point value of 12.6 kcal/mol, and it is in good agreement with experiment. The good agreement of theory and experiment for the excited state rate provides a dramatic demonstration of the reality of dynamical bottlenecks at locations far from the saddle point.

1. Introduction

Theoretical advances in chemical kinetics often require integration of several kinds of information. The combination of electronic structure and chemical dynamics calculations provides one particularly fruitful way to gain a detailed understanding of the forces responsible for observed kinetic phenomena. In our own work we have made several calculations of chemical reaction rates based on potential energy surfaces derived in whole or in part on *ab initio* electronic structure theory. Systems studied have included the reactions  $H + H_2$ ,  $OH + H_2$ ,  $O + OH$ ,  $F + H_2$ , and  $O + H_2$ .

The  $O + H_2$  reaction, unlike all the others on the above list, has more than one low-lying potential energy surface. In addition to the  $1A'$  water surface, that does not correlate adiabatically to the  $3P$  state of  $O$ , there are two  $3A'$  surfaces and a  $3A''$  one that do. One  $3A'$  surface and the  $3A''$  surface form a degenerate  $\Pi$  state for all collinear geometries but have different bend potentials: The  $3A''$  state has a significantly broader bending valley, and hence it dominates the thermal rate at most temperatures of interest, although the  $3A'$  state may make a non-negligible contribution at high temperature (1,2). The second  $3A'$  state is unimportant for the thermal reaction rate. In our previous calculations (3,4) we included only the contributions from reaction on the lowest-energy  $3A''$  surface. The collinear part of this surface was treated by the modified rotated Morse oscillator spline fit of Lee et al. (5) to the *ab initio* calculations of Walch et al. (1,2,6) and the bend potential was treated by an anti-Morse bend model (7-9) with one parameter adjusted to reproduce the harmonic bend potential at the saddle point for the same *ab initio* calculations. In the present paper we include both electronic states, and the potential energy surfaces are treated by an improved parametrization. The improved parametrization consists, for each of the two surfaces, of a three-parameter fit to the bend potential so that it agrees with the newest *ab initio* calculations (10)

for large-amplitude ( $45^\circ$ ) bends at three points along the reaction path, including both the saddle point and a point close to the vibrationally adiabatic ground-state barrier maximum. We use the PolCI calculations of Walch *et al.* (1,6,10) because (i) they are available at enough geometries to determine both potential energy surfaces in the regions important for the reaction rate and (ii) they appear reasonably accurate. We note that in our previous study (4) of the  $O+H_2$  reaction, we calculated rate constants for five potential energy surfaces. Two of these, called surfaces P and M, were based on the PolCI calculations, and the results appeared to show that these were the most accurate of the five.

The procedure used to fit the bend potential in the present study is a specific example of a strategy that may be very useful in many cases (11), namely the fitting of a globally defined potential in the wide vicinity of a reaction path with special emphasis on dynamical bottleneck locations (12) as determined by variational transition state theory (13,14) or the adiabatic theory of reactions (15).

Having obtained a representation of the potential energy surface, we calculated both thermal rate constants and state-selected rate constants for vibrationally excited  $H_2$  by variational transition state theory with semiclassical ground-state transmission coefficients (3,16-18). These methods have been shown to provide reasonably accurate estimates of the quantum mechanical local-equilibrium and state-selected reaction rates for most chemical reactions (3,13,14,19,20). In general we believe we can use these methods to calculate rate constants that are reliable for a given potential energy surface to within a factor of two or better at room temperature and above. This is sufficient to compare computed rate constants to experiment, to test *ab initio* potential energy surfaces, and to draw useful conclusions about which features of the potential energy surface are significant for determining the magnitudes of observed rate constants and kinetic isotope effects.

## 2. Potential Energy Surfaces

The  $3\pi$  potential energy surface is represented by the rotated Morse oscillator spline function of Lee *et al.* (5) for collinear geometries augmented by an anti-Morse bend (AB) potential (7-9). The parameters of the bend potential are adjusted to *ab initio* calculations (1,6,10) in the region near the saddle point and the vibrationally adiabatic ground-state barrier maximum (the maximum of  $V_A^G(s)$  in the notation used previously (12,17)). Further details are given elsewhere (21).

## 3. Dynamical Calculations

We calculated a separate rate constant for each potential energy surface. Denoting these results by  $k_{A''}$  and  $k_{A'}$  respectively, the thermal (i.e., canonical ensemble) rate constant is

$$k = k_{A'} + k_{A''} \quad (1)$$

Each of the single-surface rate constants includes a multiple-surface coefficient (22) equal to  $3/Q_A^{\ddagger}$  where 3 is the electronic degeneracy of the generalized transition state and  $Q_A^{\ddagger}$  is the electronic partition function of atomic O.

The single-surface rate constants were calculated by improved canonical variational transition-state-theory (ICVT) with semiclassical ground-state transmission coefficients. The methods are described in detail elsewhere (3,16-18). First we calculate the minimum energy path (MEP) by following the negative gradient of the potential in mass-scaled coordinates. Then for each distance  $s$  along the MEP we calculate the improved generalized standard-state free energy of activation  $\Delta G_{GT,0}^{\ddagger}(T,s)$  for a generalized transition state at this  $s$ , where  $T$  is the temperature. The hybrid ICVT rate constant for temperature  $T$  is then given by

$$k^{ICVT}(T) = \min_s \frac{\tilde{k}T}{h} k^{\ddagger,0} \exp[-\Delta G^{IGT,0}(T,s)/\tilde{k}T] \quad 2)$$

where  $\tilde{k}$  is Boltzmann's constant,  $h$  is Planck's constant, and  $k^0$  is the reciprocal of the standard-state concentration. This rate constant is a hybrid because the reaction coordinate is treated classically but other degrees of freedom are all treated quantum mechanically. In the final step we add quantum effects on the reaction coordinate by a ground-state (G) transmission coefficient  $\kappa^G(T)$ :

$$k^{ICVT/G}(T) = \kappa^G(T) k^{ICVT}(T) \quad 3)$$

We consider two methods to approximate  $\kappa^G(T)$ : the minimum-energy-path semiclassical adiabatic method (MEPSAG) (17) and the least-action method (LAG) (18). The latter accounts for the shortening of the tunneling path due to the system "cutting the corner" of the curved MEP through mass-scaled coordinates by finding the dynamically optimal tunneling path by evaluating an imaginary-action functional along a one-parameter sequence of trial paths. These vary linearly between the MEP at one extreme and a straight line through mass-scaled coordinates from the translational turning point on the MEP in the entrance channel to the translational turning point on the MEP in the exit channel at the other extreme.

Anharmonicity is included as discussed elsewhere (3,17).

The evaluation of state-selected rate constants for  $H_2$  in the  $n=1$  excited vibrational state requires further assumptions. Figure 1 shows the vibrationally adiabatic potential curves for  $n=0$  and  $1$  for the  $3A'$  surface. The potential curves in Fig. 1 are defined by

$$V_a^g(n,s) = V_{MEP}(s) + \epsilon_{str}(n,s) + 2\epsilon_{bend}^g(s) \quad 4)$$

where  $V_{MEP}(s)$  is the Born-Oppenheimer potential on the MEP,  $\epsilon_{str}(n,s)$  is the local vibrational energy of the stretching mode orthogonal to the MEP and in quantum state  $n$ , and  $2\epsilon_{bend}^g(s)$  is the local zero point energy of the twofold-degenerate bending mode. Figure 2 shows the same quantities for the  $3A'$  state. In both cases we also show the curvature  $\kappa(s)$  of the MEP through mass-scaled coordinates (17). We will consider two limits for the excited-state rate constants. The first is the adiabatic limit (4,16,18,23), in which case we perform calculations identical to those for the thermal reaction rate except that in both  $\Delta G^{IGT,0}(T,s)$  and the tunneling calculation we neglect all stretching vibrational states except the  $n=1$  state. The second treatment is a sudden nonadiabatic model explained elsewhere (21).

We will consider three reactions:

#### 4. Results

Table I shows results for two methods of calculating transmission coefficients. The MEPSAG results are based on a semiclassical adiabatic treatment of tunneling along the minimum energy path (17). As compared to the LAG method this underestimates the rate constant by a factor of 24 at 200K and a factor of 3.3 at 300K. This

confirms, as first discovered for the  $H+H_2$  reaction (24) and then found in many cases (4,13,16-19,25-31), that multidimensional effects on the tunneling probabilities are very important and reduction to a one-dimensional problem by simply straightening out the minimum-energy reaction path seriously underestimates the extent of tunneling.

Table I also compares the final thermal rate constants of this study for reaction R1) to a selection of experimental (32-34) results. For 297-472K, the table shows only the most recent experimental data (32). The ICVT/LAG rate constants are usually larger than these results but agree within 25%. Rate constants in this temperature range are very sensitive to the barrier height, and the uncertainty in the ab initio potential energy surface is certainly great enough to yield larger errors. Thus the agreement of the present calculations with experiment is better than could have been expected. Furthermore the other recent experimental measurements in this range do not all agree with those of Presser and Gordon within a factor of two. The most recent evaluation (33) of experimental data for the  $O+H_2$  reaction concludes that for  $T \geq 400K$  the expression of Baulch et al. (34) fits most of the data within experimental error. We use this expression for the experimental values at 600-1500K. In this temperature range the present calculated rate constants are all larger than these experimental results, but the ICVT/LAG results are high only by factors of 1.2-1.5. At 2400K the agreement with experiment (35) is excellent.

We also calculated thermal rate coefficients for the isotopic analog reactions and the kinetic isotope effects and compared them to experimental (32,34-37) results. Because of space limitations we simply point out here that the calculated results agree with the experimental ones within the reliability of the latter. We also calculated kinetic isotope effects by conventional transition state theory (TST). These are qualitatively similar to the ICVT/LAG results, and hence also to the experimental results, but that is at least partly fortuitous since TST greatly underestimates the individual isotopic rate constants. For example for reaction R1) the TST rate constant is a factor of 9.3 lower than the ICVT/LAG one at 300K and a factor of 2.5 smaller at 400K. The LAG transmission coefficients are even larger, 12.6 at 300K and 3.1 at 400K, but the lack of quantal effects on reaction-coordinate motion in conventional TST is partly compensated by the lack of variational minimization of the hybrid rate constant with respect to the location of the generalized transition state. Then a further cancellation of errors occurs in the kinetic isotope effect ratio.

The adiabatic and sudden nonadiabatic rate constants for reaction R1) with vibrationally excited  $H_2$  are very similar for the present potential energy surface; thus we tabulate only the adiabatic values. The rate constants calculated by the adiabatic theory for reaction R1) when  $H_2$  is excited to the  $n=1$  vibrational state are given in Table II. We see that the transmission coefficients (ratios of ICVT/LAG tunneling-corrected rate constants to ICVT hybrid ones) are 2.6-2.7 at 302K, which are very significant factors but are smaller than for the thermal reaction rate. At 302K the calculated vibrational enhancement factor in the ICVT/LAG approximation is  $1.4 \times 10^3$  by Light (38), but it is only  $8.2 \times 10^2$  times larger than the interpolated value of Presser and Gordon (32). The agreement of theory with experiment is satisfactory.

Table III shows some of the properties of the dynamical bottlenecks for the vibrationally excited reaction. The variational transition states are farther from the saddle point ( $s=0$ ) for the vibrationally excited reaction than for the thermal reaction. Similar results have been found previously for  $H+H_2$  (23) and  $OH+H_2$  (39) for vibrationally excited reactants. This means that the improved parametrization of the bend potential for geometries far from the saddle point becomes more important for  $n=1$ . It also means that conventional TST becomes worse. Conventional TST predicts a vibrational enhancement factor of  $2.5 \times 10^5$  at 302K, which is two orders larger than the accurate values. The good agreement of the ICVT/LAG values with experiment provides a dramatic demonstration of the reality of dynamical bottlenecks at locations far from the saddle point.

## FUNDAMENTALS OF NITRIC OXIDE FORMATION IN FOSSIL FUEL COMBUSTION

Thomas J. Houser, Michael E. McCarville and Gu Zhuo-Ying

Chemistry Department, Western Michigan University  
Kalamazoo, MI 49008

### INTRODUCTION

Combustion of fossil fuels in large stationary furnaces causes the emission of nitrogen oxides, a large fraction of which arise from the nitrogen-containing components in the fuel, producing a major pollution problem which is expected to increase in severity in the future. The results being reported in this paper are part of those obtained from a continuing study to determine the mechanism by which these oxides may form. Because studies have shown that most of the nitrogen in heavy oils is in the form of heterocycles (1-3) and it is believed that the nitrogen components of coal are similar, pyridine was selected as representative of these components. It was assumed that the radical fragments formed during pyridine pyrolysis and rich, low temperature oxidation would be similar to those obtained from the same reactions of fossil fuels that occur during the pre-flame stages of combustion. Later experiments emphasized HCN oxidation since several studies indicated that it was the key volatile, nitrogen-containing intermediate formed during fuel nitrogen combustion (4-8). In addition, HCN used with several fuel additives allowed a greater control of the chemical nature of the reaction environment. We have previously reported on the inert pyrolysis kinetics of pyridine (9), the rate of formation of HCN during pyridine pyrolysis (10), the oxidation kinetics of cyanogen (11), and of pyridine (12) and HCN (13) at low temperatures.

### EXPERIMENTAL

A flow system designed to operate at atmospheric pressure was constructed for the study of the oxidation of the pertinent nitrogen-containing reactants. The system is suitable for the introduction of volatile liquids (reactants and solutions with additives) into a heated helium stream through the use of a syringe pump to drive a calibrated, tuberculin syringe. The system can also utilize gaseous species; these reactants and additives, mixed with helium at the desired concentrations, are maintained in steel storage tanks. The flow stream is examined by a quadrupole mass analyzer equipped with capillary probe atmospheric sampler which functioned as an on stream monitor for the consumption of reactants. Helium is used as the carrier gas because it is chemically inert and has a very high thermal conductivity, thus providing rapid heating and quenching. The system has a group of removable Vycor reactors heated by an electric furnace. One reactor was a stirred-flow design (40 cc) which had been previously tested for stirring efficiency (14), the others were plug-flow type (10 to 40 cc). A flow line which bypasses the reactor was used so that entrance and exit concentrations of reactants could be measured. A Thermo Electron Chemiluminescent NO/NO<sub>x</sub> analyzer with on stream sampling was used for the oxidation studies of pyridine, HCN and N<sub>2</sub>O. A modification of the flow stream was required to obtain direct samples from the reactor effluent to measure the light gases with a gas chromatograph. A linear switching valve was used to provide a series-bypass capability with

constant back pressure for the two columns. A molecular sieve 5A column was used for  $O_2$ ,  $N_2$  and CO while a porous polymer Chromosorb 101 column was used for  $CO_2$  and  $N_2O$ . In order to determine the amounts of HCN and  $NH_3$  produced from the oxidation of pyridine and HCN, dilute solutions of NaOH or HCl in the bubble towers were used in separate experiments to trap the HCN or  $NH_3$  respectively, for ion-specific electrode analysis. A second bubbler in series with the first was found to be unnecessary.

## RESULTS AND DISCUSSION

The current study has shown that in order to produce significant yields of NO from the oxidation of pyridine or HCN-fuel mixtures, conditions which promote a flame must exist in the flow reactor. The existence of a flame was confirmed by visual observation in several, but not all, experiments. The capability of producing a flame depends on the nature of the fuel (Tables 1, 2 and 3, all data are stirred-flow), temperature (Tables 1, 2, 3 and 5), concentrations (Tables 1-5), reactor design (stirred - or plug-flow, Table 5), and flow rate (Tables 1 and 5). The conditions which promoted NO formation were characterized by complete consumption of fuel-nitrogen at all flow rates in the stirred-flow reactor, however, the plug-flow reactor exhibited an inverse consumption at intermediate temperatures, at first decreasing from complete consumption at high flows, passing through a minimum then increasing again (Table 5,  $C_5H_5N$  and HCN/ $C_6H_6$  mixtures at 800 C and HCN/CO at 700 C) while the NO yield continually decreased. After a threshold temperature was reached in the plug-flow reactor, the NO yield did not appear to depend on temperature significantly (Table 5). The non-flame conditions, at relatively low temperatures and/or concentrations of fuels, were characterized by a flow rate dependent consumption of fuel-nitrogen which was converted essentially completely to  $N_2$  and  $N_2O$  (maximum yield of about 50% of the latter) (12, 13). This was observed in both types of reactors, however, the flame condition persisted to a much lower temperature in the entrance of the plug-flow reactor as evidenced by visual observation and NO production. The observed dependence of NO yields on flow rate, first increasing to a maximum then decreasing (Tables 1, 2 and 5) in the stirred-flow reactor was not observed with plug-flow, thus is thought to be an anomaly due to reactor-induced flame instability. However, other yield dependencies are qualitatively the same in both types of reactors. The transition between flame and non-flame reaction was abrupt as evidenced by a rapid increase in fuel nitrogen consumption and shift in products, thus is attributed to a change in mechanism rather than a sequential process.

Specifically it was found that pyridine and benzene/HCN mixtures give similar results (Tables 1, 2 and 5) while CO (Tables 2 and 5) and acetylene (13) added to HCN promoted NO formation at lower temperatures and concentrations (on an atom or heat equivalent basis), than the other fuel combinations. Mixtures of  $H_2$ /HCN were very different from other fuel combinations, producing lower extents of HCN consumption and very low to negligible yields of NO at conditions which normally gave high yields of NO with other fuels (Table 1). Finally, it has been clearly established that  $N_2O$  was the prevalent oxide of nitrogen at low temperatures (Table 5 and Reference 15) and/or equivalence ratios (Table 4), whereas NO became prevalent at higher temperatures and fuel concentrations (up to stoichiometric mixtures) and that their concentrations were inversely related. In order to further check the possibility of NO/ $N_2O$  interconversion experiments were performed by adding  $NO_2$  (NO did not exist in our reactant storage tank) to the

reaction mixture at low temperatures and by oxidizing  $N_2O$  in the presence of various fuels (Table 7). The results with  $NO$  were somewhat inconclusive since some experiments showed some increase in  $N_2O$  and others did not (16). The relatively small increases observed indicate that  $NO/NO_2$  could not be a major source of  $N_2O$  at those conditions. The results with  $N_2O$  clearly show that  $NO$  is not formed from  $N_2O$  in large yields.

In addition to the volatile products observed, it was noted that a white solid was formed (about a 3% yield) at non-flame conditions with lean mixtures of  $HCN/CO/O_2$  and  $HCN/H_2/O_2$ . Samples of these solids were examined by infrared and elemental analyses which indicated that those from  $HCN/CO$  were  $NH_4NCO$ , whereas most, but not all, of those from  $HCN/H_2$  were urea (Table 8). It was also found that a room temperature sublimate from  $NH_4NCO$  was urea, indicating an easy conversion was possible. These solids show the presence of  $NH_3$  and  $HNCO$  in the reactor at non-flame conditions. In an attempt to determine the nature of the intermediate that leads to  $N_2O$  formation, oxidation studies of methylisocyanate and dimethylhydrazine, with and without additive fuels, were made. No increase in  $N_2O$  formation was noted from these over that obtained from  $HCN$ .

#### CONCLUSIONS

The conclusions reached from the above observations are: (1) That  $N_2O$  and  $NO$  are probably formed from a common precursor in the mechanistic chain, although possibly not the same immediate intermediate, and neither are formed from each other. The data strongly shows that  $NO$  does not form at those lower temperatures which promote  $N_2O$  formation and  $N_2O$  does not oxidize to  $NO$ . In addition, the equivalence ratio dependence shows that  $N_2O$  forms at leaner conditions than does  $NO$ , which is most likely due to maintenance of flame conditions at the more rich conditions. Thus, the reported mechanism steps for the formation of  $N_2O$  from  $NO$ , at least at our conditions, are not applicable (17). (2) That  $NO$  formation cannot occur primarily by an interaction between  $NH$  or  $N$  and  $OH$ , as usually assumed in mechanisms (17), because of the observed influence of different fuels on the conditions necessary to produce  $NO$ .

Kinetics of the Reaction of NCO with Ethene and Oxygen  
Over the Temperature Range 295-662K\*

Robert A. Perry

Sandia National Laboratories  
Combustion Research Facility  
Livermore, California 94550

Introduction

The NCO radical is intimately connected with nitric oxide formation from fuel-bound nitrogen in combustion systems.<sup>1,2</sup> In order to model nitrogen chemistry in combustion systems, it is essential to explore the possible chemical reactions that might enter into any extensive model of nitrogen chemistry in these systems. While little has been done toward understanding the detailed chemistry of the NCO radical with combustion species,<sup>1-5</sup> certain reactions can be anticipated to occur based upon analogous electrophilic radical/molecule reactions. One of these reactions is the reaction of NCO with ethene.

Unsaturated hydrocarbons are found extensively in combustion, with ethene being a major component after pyrolysis of larger fuels. This reaction was chosen to facilitate predictions of NCO radical reactions with unsaturated hydrocarbons and hence to understand more fully nitrogen chemistry in rich combustion systems. To the extent that this reaction occurs at combustion temperatures, it is a pathway to recycle reactive nitrogen radicals back into fuel-bound nitrogen i.e., HCN.

Other possible important reactions, if they occurred, are the exothermic reactions of NCO with oxygen.

Besides being of potential importance in combustion systems, these reactions could be important in atmospheric oxidation of HCN. An upper limit has been placed on the exothermic, although sterically restricted, reactions between NCO and oxygen.

In this paper current research that employs a laser photolysis/laser-induced fluorescence technique to measure absolute rate constants for the reaction of NCO radicals with ethene and oxygen over the

temperature range 295-662K is discussed. In addition, the pressure dependence of the reaction between NCO and ethene is explored at room temperature. The implications for combustion modeling will be addressed.

#### EXPERIMENTAL

The technique is essentially identical to that which was developed to study the products of the reaction of  $O(^1P)$  with HCN.<sup>6</sup> NCO radicals are produced from the excimer laser photolysis of HNCO that was introduced along with the reactant of interest in a flowing gas mixture of HNCO:Ar:reactant at total pressures (primarily argon) of 10-372 Torr. The NCO radicals result either directly from the photolysis of HNCO or, as suggested by Drozdowski et al.,<sup>7</sup> from the rapid reaction of  $NH(^1\Delta)$  with HNCO. (Recent experiments at 157 nm and 193 nm suggest that the latter is the dominant mechanism.<sup>8</sup>) Both 193 nm and 157 nm radiation are used to photolyze HNCO in order to check for interference due to photolysis products.

An argon ion pumped ring dye laser, operating with stilbene-3 dye at 416.8 nm (100mW), is used to pump the  $A^2\Sigma(1,0,0) \leftarrow X^2\Pi(0,0,0)$  transition of NCO. The resulting fluorescence is monitored using an EMI 9789QA photomultiplier tube fitted with an interference filter at 438.5nm (FWHM=8.0nm) mounted at right angles to the crossed laser beams. The intersection of the detection system aperture and the laser-induced fluorescence radiation defined a fluorescence viewing zone at the center of the reaction vessel whose cross section was ~2cm in diameter. This region was well separated from the reaction vessel walls, minimizing wall losses of the NCO radicals. The reactor consisted of a quartz reaction vessel enclosed in a ceramic furnace that could be heated to temperatures as high as 1200K. The temperature of the furnace was monitored by Chromel/Alumel thermocouples mounted inside the reaction vessel, with the temperature of the vessel maintained to  $\pm 5K$  over the entire temperature range.

The HNCO was synthesized according to the procedure of Okabe.<sup>9</sup> Cyanuric acid was heated in an evacuable pyrex vessel to 400K. The HNCO generated was passed through a  $P_2O_5$  and  $Ag_2O$  trap to remove the water, and HCN and was then condensed in a liquid nitrogen trap. The liquid was vacuum distilled using a dry-ice/acetone trap until constant vapor pressure (0.88 Torr) resulted. Argon was bubbled through the liquid and the resulting Ar/HNCO mixture was flowed to the reaction vessel. The flow rate was monitored by use of a rotameter. All other flows were monitored by the use of Tylan flow controllers that were calibrated prior to use.

The excimer laser intensity was varied by a factor of 2 using a purge tube situated between the excimer laser and the reaction vessel. Mixtures of nitrogen and oxygen were used to attenuate the 157 nm radiation, while nitrous oxide and air were used to attenuate radiation at 193 nm. All experiments were performed at a repetition rate of 0.3Hz. Signals were obtained by photon counting in conjunction with multichannel scaling. Decay curves of NCO radicals were accumulated from 25-500 pulses

depending on the signal strengths. NCO half-lives ranged from 2.43-200 msec, and the NCO radical concentrations were followed for at least three half-lives.

All experiments were carried out under slow-flow conditions so that the premixed reactant gas mixture could be replenished between laser pulses, thereby avoiding the accumulation of photolysis or reaction products. The partial pressure of HNCO was approximately 1.8-19 mTorr. The gases used had the following purity levels according to the manufacturer: Ar  $\geq 99.995\%$ ;  $C_2H_4 \geq 99.0\%$ ;  $O_2 \geq 99.9995\%$ .

## RESULTS AND DISCUSSION

Over the entire temperature range 295-652K, and in the presence of excess reactant gas, pseudo-first order kinetics is observed, and the bimolecular rate constant is obtained using the expression:

$$\ln [NCO]_0 / [NCO]_t = \ln S_0 / S_t = (k_0 + k_i [\text{Reactant}])(t - t_0)$$

Here  $[NCO]_0$  and  $[NCO]_t$  are the concentrations of NCO radicals at times  $t_0$  and  $t$ , respectively,  $S_0$  and  $S_t$  are the corresponding fluorescence intensities,  $k_0$  is the first order rate coefficient for removal of the NCO in the absence of added reactant, and  $k_i$  is the rate constant for reaction with the added reactant, i.e., ethene or oxygen.

The decay was analyzed following a  $\sim 1$  ms delay after the excimer laser pulse to minimize interference from laser-induced emission from the silica vessel and to ensure that secondary reactions of other radical species formed during the photolysis event, such as  $NH(^1\Delta_7)$  would not interfere with the reaction of interest. In all experiments exponential decays were observed after the first millisecond supporting the contention that secondary reactions were not important. Also, at low pulse energies ( $\leq 1$  mJ/pulse) no effect, within experimental uncertainty, due to laser intensity was observed with a factor of two change. (Without attenuating the excimer laser radiation the apparent rate was measured to be faster and decays were nonexponential.)

The data were analyzed by numerical least squares fitting of the decays. The measured decay rates were found to depend linearly on the concentration of added reactant for fixed total pressure and temperature. The absolute rate constants were determined by plotting the measured decay rate against reactant concentration and performing a least squares fit to obtain the slope,  $k_i$ .

Rate constants,  $k_1$ , for the reaction of NCO with ethene were determined over the temperature range of 295-652K with the total pressure being varied from 10-372 Torr at 295K. Figures 1 and 2 show the plots of the data at 295K and higher temperatures, respectively, while Figure 3 shows a plot of the pressure dependence. Table I gives the rate constants determined for this reaction by least squares analysis over the entire temperature range.

Figure 4 shows an Arrhenius plot of the rate constants  $k_1$  with the region from 295-447K being described by the following Arrhenius expression:

$$k_1 = 3.0 \times 10^{-12} e^{(230 \pm 300)/RT} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1},$$

where the error limit in the activation energy is the estimated overall error limit.

The pressure dependence observed at 295K (figure 3) is best explained by a Lindemann mechanism.

where  $\text{complex}^*$  is the complex formed by the terminal addition of NCO to ethene. The pressure dependent rate is given by the expression:

$$k_{bi} = k_a k_b [M] / (k_{-a} + k_b [M])$$

In the high pressure region where  $k_b [M]$  is much greater than  $k_{-a}$ ,  $k_{bi} = k_a$ , while in the low pressure region  $k_{bi} = k_a (k_b [M] / k_{-a})$ .

At temperatures greater than 447K a dramatic reduction in the bimolecular rate constant was observed. As seen in Figure 4 the reaction rate drops by greater than two orders of magnitude from 447K to 652K. This reduction in bimolecular rate constant apparently occurs due to the very rapid decomposition of the complex formed between NCO and ethene. Although such a dramatic reduction in reaction rate has been observed in the past for OH radical reactions, <sup>10-14</sup> nonexponential decays (after 1ms) were not apparent in these experiments. The absence of nonexponential decays suggest that the life time of the complex formed must be short in comparison to the experimental observation time. A proposed reaction mechanism whereby the thermalized adduct, [complex], begins to dissociate on a time scale that is comparable to the time frame of the experiments, analogous to the explanation of the effect observed for OH radical reaction with unsaturated hydrocarbons, <sup>10-14</sup> could explain the sharp drop in rate with increasing temperatures ( $\geq 447\text{K}$ ), but in order to explain fully the essentially exponential decays observed in all of the experiments, competitive reactions that turn off at higher temperatures (or a different reaction mechanism that regenerates NCO radicals at higher temperatures) is required. Calculations are presently under way to address the possible alternate channels, such as ring closure to form the ethylene imine analog.

Using 193nm photolysis of H<sub>2</sub>NCO, with a mixture of nitrous oxide and oxygen as a UV attenuator/filter, the reaction of NCO with oxygen was not observed to occur at room temperature and 372 Torr argon with

$2.27 \times 10^{16}$  molecule/cm<sup>3</sup> of oxygen added. In addition no reaction was observed at 662K and 389 Torr when  $2.4 \times 10^{16}$  molecule/cm<sup>3</sup> of oxygen was added. From these data the rate of reaction with oxygen was estimated to be less than  $1 \times 10^{-16}$  cm<sup>3</sup>molecule<sup>-1</sup>s<sup>-1</sup> at 295 and less than  $5 \times 10^{-17}$  cm<sup>3</sup>molecule<sup>-1</sup>s<sup>-1</sup> at 662K. These data suggest that under the conditions that exist in combustion environments or in the stratosphere, it is unlikely that the reaction of NCO with oxygen will be important. As suggested by Cicerone and Zellner<sup>13</sup>, the primary fate of NCO in the atmosphere is most likely photolysis at wavelengths less than 300 nm.

#### CONCLUSIONS

At low temperatures the NCO radical will react with ethene to form a complex. At temperatures greater than 450K a marked decrease in the rate of reaction occurs until finally at 650K the reaction has decreased by two orders of magnitude. This effect suggests that the reaction with ethene, or, by inference, other unsaturated hydrocarbons, will not serve to recycle the NCO radical in combustion environments.

At the temperatures of this study NCO radicals do not react with molecular oxygen. The reaction of NCO with oxygen should be unimportant in combustion or atmospheric systems.

#### ACKNOWLEDGEMENT

This work was supported by the U. S. Department of Energy, Office of Basic Energy Sciences. I would like to thank Mark Jaska for his assistance in carrying out the experiments.

# Pyrolysis of C<sub>6</sub>H<sub>6</sub>

by

M. B. Colket, III

United Technologies Research Center  
Silver Lane, East Hartford, CT 06108

## Introduction

Several mechanisms for the pyrolysis of benzene at elevated temperatures have been previously proposed. Unfortunately, none of these mechanisms is entirely satisfactory when both experiments and thermodynamics are considered. Yet, knowledge of benzene decomposition will increase the understanding of the breakup and formation of other aromatic compounds. Consequently, a single-pulse shock tube (SPST) investigation of the pyrolysis of benzene has been performed over the temperature range of 1200 to 2400K. In addition, thermochemical estimates and detailed chemical kinetic modeling have been performed to evaluate the previously proposed mechanisms for benzene pyrolysis.

## Description of Facilities and Model

The 3.8 cm (i.d.) single-pulse shock tube (SPST) used in this experiment utilizes the "magic hole" technique for quenching pyrolyzed samples at rates above 10<sup>5</sup> K/sec. SPSTs were developed by Glick, Squire, and Hertzberg (1) and the UTRC facility has been described by Colket (2). Gas samples, after dwell times of approximately 700 microseconds, were automatically collected and analyzed for reactant and products using heated gas sampling valves and a Hewlett Packard 5880A gas chromatograph. With a CP Sil 5 CB (from Chrompack, Inc.) capillary column and a silica gel packed column, H<sub>2</sub> and hydrocarbons up to C<sub>10</sub> were identified and quantitatively analyzed.

Argon (99.999% pure) was obtained from Matheson and LC-grade benzene was obtained from the Burdick and Jackson Laboratory. The initial mixture concentration was 130 ppm benzene in argon and was prepared gravimetrically. Gas chromatographic analysis indicated that impurities included unidentified C<sub>5</sub>, C<sub>6</sub> and C<sub>7</sub> hydrocarbons as well as toluene, although the total concentration of impurity was less than 0.2% of the initial benzene.

Detailed chemical kinetics calculations are performed using CHEMKIN(3), LSODE (4), and a version of a shock tube code (5) which has been modified to include the quenching effects in a SPST. Quenching rates varied with shock strength and were calculated using measured pressure traces and assuming isentropic expansion. The modified code also allows monitoring of time-dependent contributions from each reaction to the formation and/or destruction of each species.

### Proposed Mechanisms

Mechanisms for the decomposition of benzene are listed in Table I. It is important to note that most are not single-step mechanisms. Radical intermediates equilibrate rapidly and their concentrations are sufficiently low to render them (nearly) undetectable in many systems. Experimental results from the present and previous high temperature works (6,7) suggest that primary stable products are acetylene, diacetylene, and hydrogen and the initial production rate of acetylene is two to three times higher than that of diacetylene. Unfortunately, this information is of minimal use in sorting out the mechanisms since benzene pyrolyzes at high temperatures (relative to pyrolysis temperatures of other hydrocarbons) and all intermediates shown in Table II rapidly pyrolyze to the approximate mixture of acetylene and diacetylene that has been observed.

Mechanism A is the generally accepted reaction sequence; however, only Reaction 1 is understood. The breaking of the C-H bond is believed to be the initiation step in both pyrolytic and some oxidation studies. Its rate has been determined from D-atom production (in pyrolysis of  $C_6D_6$ ) (8) and from detailed modeling studies of both pyrolysis (9) and oxidation (10). An RRKM fit has been performed by Kiefer, et al (9) using available experimental data and is consistent with thermodynamics. Their  $k_1^0$  is given by  $10^{17.3} \exp(-118 \text{ kcal/RT}) \text{ sec}^{-1}$ . Knowledge of the mechanism for phenyl decomposition is substantially less than that for Reaction 1. Some information is available on the overall rate,  $k_3$ ; yet the details of the ring fracturing process have not been defined. The thermochemical estimate by Fujii and Asaba (11) has been until recently the most often quoted rate for this process. More recent modeling (8,9) of benzene pyrolysis has produced similar rates as Ref. 11; however, since Reaction 1 is rate limiting over most of the temperatures regimes examined, the modeling results for  $k_3$  are expected to be lower limit estimates with large uncertainties in the temperature dependence. The Fujii and Asaba (11) estimate,  $k_3 = 3.16 \times 10^{14} \exp(-86 \text{ kcal/RT}) \text{ sec}^{-1}$ , was based on an "old" value for the heat of formation for  $i-C_4H_9$  of 102 kcal/mole (12); however, more recent estimates using group additivity (13) and BAC-MP4 (14) techniques fix this value closer to 115 kcal/mole. In addition,  $n-C_4H_9$ , which has a  $\Delta H_f^\circ$  of 126 kcal/mole, is the preferred isomer for phenyl decomposition. Consequently, Reaction 3 is over 100 kcal/mole endothermic. If this process involves direct  $C_2H_2$  elimination, then the previous modeling efforts that produced lower limit rates strongly suggest that the high pressure A-factor is at least  $10^{17.8}$ . This value is orders of magnitude higher than what would be expected for this multibond process. Consequently, it must be assumed that Reaction 3 represents an overall process or that processes involving radicals other than, or in addition to, phenyl are important to benzene decomposition.

One alternative route for benzene decomposition is direct  $C_2H_2$  elimination (Mechanism B) and has received recent support (6,8); however, Kiefer, et al (9) have shown it is not necessary to invoke this step to describe experimental profiles. In addition, it should be noted that the direct elimination is a multibond process which should be unlikely, and presumably involves the intermediate formation of the  $C_4H_4$  diradical. For this intermediate, the effective activation barrier to Reaction 4 may be as high as 180 kcal/mole.

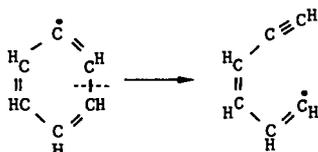

Another possible pyrolysis route involves the production of benzyne, which subsequently decomposes. Unimolecular decomposition of phenyl (Reaction 5) to benzyne is endothermic by 93 kcal/mole, which is nearly as much as Reaction 3. Similar thermochemical arguments can eliminate this decomposition route. The other route, Reaction 6, is a radical termination step and would produce an overall slowing of benzene pyrolysis. Knudsen cell pyrolysis experiments (7) have shown the formation of a  $C_6H_4$  compound. Assuming this compound is benzyne or another product of phenyl decomposition, Smith and Johnson (7) argued that  $C_6H_4$  is an important intermediate during benzene decomposition, especially at elevated temperatures. At least some of the product, however, may be composed of the chained isomers of  $C_6H_4$ . These isomers may be produced via hydrogenation of triacetylene, which was also observed in significant concentrations. Consequently, no clear evidence of the importance of Mechanism C is apparent.

Mechanism D appears to be very attractive, since an extrapolation of the rate coefficient (15) for H-atom addition to benzene (Reaction 8) is approximately an order of magnitude higher (Ref. 9) than H-atom abstraction (Reaction 2) at 1600 K. The addition reaction, however, competes with its reverse reaction. Using thermodynamics for  $c-C_6H_7$ , derived from measurement of the forward and reverse rates of Reaction 8 (15), Mechanism D can be shown to have a negligible impact on benzene pyrolysis. However, a different set of thermodynamics for  $c-C_6H_7$ , reported in Ref. 15 suggests that Mechanism D may play an important role at low temperatures. Detailed modeling calculations using Mechanism D were limited, due to what appears to be rather large uncertainties in both the heat of formation and entropy. Nevertheless, there are attractive features of this decomposition mechanism, especially at low temperatures, and it should be explored further. It is worth noting that Reaction 8 is not sufficiently energetic (only 16 to 26 kcal), that it can be followed immediately by Reaction 9 (71-81 kcal required). Instead,  $c-C_6H_7$  will collisionally thermalize prior to its decomposition to products. Only a minimal acceleration in rate due to the formation of an excited complex can be expected. Further exploration of this route (Mechanism C) should be performed.

With no fully satisfactory alternatives, and the expectation that phenyl must decompose to aliphatics at sufficiently elevated temperatures (when production of phenyl via Reaction 1 is fast), it is prudent to re-examine Mechanism A. One can separate Reaction 3 into the following sequence:

This sequence is the reverse of the processes suggested for the formation of phenyl during acetylene pyrolysis (17) and has been shown to compare favorably with recent experimental data (2). If one assumes that the ring breaks at the single bond as shown

then this is a relatively straightforward process analogous to the decomposition of  $n\text{C}_6\text{H}_5$ ; i.e.  $\text{CH}:\text{CH}:\text{CH}:\text{CH}_2 + \text{C}_2\text{H}_2 + \text{C}_2\text{H}_3$ . Breakage of either of the other two single-bonds would require a more complex process involving H-atom shifting or the formation of energetic intermediates. The resultant linear compound would be expected to decompose to acetylene and  $n\text{-C}_4\text{H}_3$  or re-cyclize to phenyl. Detailed chemical modeling was performed using the reaction sequence in Table II coupled with an acetylenic mechanism similar to that reported (17, 18). A comparison of the model and single-pulse shock tube data is presented in Figure 1 for a series of shocks at an initial concentration of 130 ppm benzene in argon. In this figure, final concentrations produced after a dwell time of 700 microseconds followed by quenching are plotted as a function of initial post-shock temperature. Total pressure for these experiments is approximately seven atmospheres.

The comparison is quite reasonable. The higher fractional decomposition at low temperatures observed in the experiment may be due to impurities from the wall initiating the reaction at low temperature. The residual benzene observed experimentally at elevated temperatures may be caused by sampling a portion of the boundary-layer near the walls of the shock tube. The mechanism proposed in Table II is essentially consistent with Kiefer et al's except that Reaction 3 has been separated to 3a and b. An effective rate constant for Reaction 3 can be estimated by assuming a steady-state concentration for  $1\text{-C}_6\text{H}_5$ , i.e.

$$[1\text{-C}_6\text{H}_5]_{\text{s.s.}} = \frac{k_{3a}[\text{C}_6\text{H}_5]}{(k_{-3a} + k_{3b})}$$

therefore  $k_3$  effective =  $\frac{k_{3a} k_{3b}}{k_{-3a} + k_{3b}}$

This curved evaluation is depicted as a solid line in Fig. 2 over the temperature regime where sensitivity to this rate was observed. The curve is extrapolated to both low and high temperatures to facilitate comparisons to other evaluations. The relatively high values obtained in this work for  $k_1$  and  $k_3$  effective are not surprising since the rate constant determined in these experiments are expected to be close to the high pressure limiting value.

#### Conclusions

Previously proposed mechanisms for the pyrolysis of benzene at high temperatures have been reviewed using detailed chemical modeling and a brief thermochemical examination. The most widely accepted sequence,  $\text{C}_6\text{H}_6 \rightarrow \text{C}_6\text{H}_5(+\text{H}) \rightarrow \text{C}_4\text{H}_2 + \text{C}_2\text{H}_2$ , is slightly modified to  $\text{C}_6\text{H}_6 \rightarrow \text{C}_6\text{H}_5(+\text{H}) \rightarrow 1^4\text{C}_3\text{H}_5^{2-2} \rightarrow n\text{-C}_4\text{H}_3 + \text{C}_2\text{H}_2$ , and the structure of the linear  $\text{C}_6\text{H}_5$  intermediate is proposed. Forward and reverse rates are consistent with thermochemistry and experimental data. A benzene decomposition route involving  $c\text{-C}_6\text{H}_7$  and  $1\text{-C}_6\text{H}_7$  was examined, yet sufficiently accurate thermochemistry was not available to reach final conclusions.

INTRODUCTION:

The production of intermediate and large hydrocarbon species is common to most combustion systems. These products range in size from acetylene, benzene and polynuclear aromatic hydrocarbons (PAH) to very large soot particles. Radiation from particles is the dominant mode of heat transfer in large fires. In addition, sampled particles often have PAH adsorbed onto them. Many of these molecules are known carcinogens and their presence on inhalable soot particles poses an obvious long-term health hazard. Despite the important role that such species play in flames and the danger they present as combustion byproducts, the mechanism for their formation is as yet unknown.

Extensive profile studies have led to a detailed understanding of the chemical structure of premixed flames [1]. This information has been combined with the time-temperature history in these one-dimensional systems to produce simple models for the condensation chemistry of premixed flames. Modelling efforts have also been undertaken in shock tubes, although the data set available as input has generally been less extensive [2,3]. Despite the significant progress towards an understanding of soot formation which has resulted from these studies, most practical combustion devices are diffusion flames, and chemical structure data for these environments has only recently been available. Workers in this [4] and other [5] laboratories have recently reported concentration measurements for molecular species, including intermediate hydrocarbons, in laminar diffusion flames. Our work has shown that a knowledge of the local chemical composition alone is not sufficient to predict the concentrations of PAH and soot. We have therefore also collected profile data for temperature and convective velocity in our flame system. In this paper, results for the chemical structure of a methane/air diffusion flame are reviewed. Species concentrations are combined with profiles of velocity and temperature to calculate production rates for intermediate hydrocarbons. The relevance of these calculations to an understanding of soot formation chemistry is discussed.

#### EXPERIMENTAL APPROACH:

The experimental system has been described in detail elsewhere [4], and will be discussed only briefly below. Laminar methane/air diffusion flames were burned at atmospheric pressure on a Wolfhard-Parker slot burner. Fuel exits a central 8mm wide slot and air flows through two 16mm wide adjacent slots. Thus, two flame sheets are formed near the fuel/air interfaces, which are symmetric about the burner centerline. The flame is stabilized by wire screen "gulls" located 45mm above the burner surface. Concentration profiles of numerous stable flame species were collected via a direct-sampling mass spectrometer equipped with a quartz microprobe [6]. Calibrations were performed by measuring the signal for a particular molecule sampled from a mixture of known composition of the species with argon at room temperature. Calibration factors were then corrected for the variation of the mass flow through the sampling orifice as a function of temperature. For species which could not be calibrated directly, factors for similar species were adjusted by multiplying by the ratio of their respective ionization cross-sections.

Temperature profiles were measured with an uncoated fine wire Pt/Pt-10%Rh thermocouple. Corrections due to radiation effects are less than 7% at the highest temperatures in this flame [4], while catalytic effects are expected to be small [7] and in the opposite direction. Horizontal and vertical components of the convective velocity were determined using laser Doppler velocimetry. These measurements were made by seeding the flow with nominal 1  $\mu$ m diameter aluminum oxide particles. The temperature and velocity profiles were obtained at heights ranging from near the burner surface to 20 mm above the burner. Mass spectrometric measurements were limited to a minimum height of 3 mm above the burner (due to the 6mm diameter of the microprobe) and a maximum height of 15 mm above the burner. Above 15 mm, clogging of the probe orifice by soot particles was observed and quantitative sampling was no longer possible. The gradients in concentration and temperature in this flame are steepest in the horizontal direction. Therefore, profile data points were collected every 0.2 mm in the lateral direction and every 2 mm in the vertical direction.

#### RESULTS:

Figure 1 illustrates the temperature and velocity fields for this flame. Shown in solid lines are isothermal contours determined from the thermocouple profiles. Note the bowing out of the flame along the 1900 K contour away from the slot separators located at  $\pm 4$  mm with respect to the burner centerline. Also shown are streamlines of convective velocity calculated from the two measured velocity components. The streamlines exhibit trajectories which begin in the lean region of the flame, cross the high temperature reaction zones, and continue into the fuel-rich regions.

Figure 2 shows mass-spectrometric profiles of the concentrations of a variety of stable flame species at a height of 9 mm above the burner. A number of points are noteworthy in comparing

Figures 1 and 2. First, the concentrations of oxygen and methane disappear near the high temperature reaction zone at  $\pm 6$  mm from the burner centerline, where the concentration of water is at a maximum. Second, the high concentration of nitrogen near the burner centerline reveals that significant entrainment of air (as shown by the velocity measurements in Fig. 1) and diffusion of nitrogen toward the burner centerline occur. Also shown in Fig. 2 is a summation of mole fractions for all species present in the flame at a concentration of 1% or greater. The close agreement to an ideal mass balance of 1 throughout the flame is a measure of the success of our calibration scheme.

Figure 3 illustrates profiles collected at 9mm above the burner surface for a variety of intermediate hydrocarbons: acetylene, benzene, diacetylene, and butadiene. Peak concentrations at this height for these species are 6200, 800, 570, and 110 parts per million, respectively. Profiles for a large number of additional intermediate hydrocarbons were obtained, and all have concentration maxima in the same region of the flame.

#### DATA ANALYSIS

One of the primary goals of our work is the application of kinetic modelling to a methane/ air diffusion flame. The approach we have adopted is to compare the predictions of models which have been used successfully in premixed flames and shock tubes with our experimental results. A successful model must not only account for the steady state concentrations of species involved in the soot formation process, but also for the net rate of reactions for these species in the flame. Therefore, as a first step in the application of detailed kinetic modelling to our flame we have sought to derive the net chemical flux for profiled species from our concentration, temperature and velocity measurements. The procedure for this calculation is described below.

A laminar flame is a steady-state system: the value of any macroscopic variable (such as a species concentration) does not change with time at a particular spatial location [6]. Because there is a flux into and out of a given volume element due to mass transport, there must be a corresponding change in the species concentration due to chemical reactions:

$$R_i = \nabla [N_i (v + V_i)] \quad 1)$$

Here,  $R_i$  is the net chemical rate,  $N_i$  is the species concentration,  $v$  is the mass average (convective) velocity, and  $V_i$  is the diffusion velocity of the species into the local mixture. This diffusion velocity can be calculated by first computing the effective diffusion coefficient,  $D_{i,mix}$ , where contributions from all species present in the flame with a concentration greater than 1% are included:

$$V_i = - \frac{D_{i,mix}}{x_i} \cdot \nabla x_i \quad 2)$$

Figure 4 illustrates this calculation for acetylene production rates at a height of 9mm above the burner. Contributions from the convective and diffusive velocities to the net chemical rates are shown. Note the strong diffusive velocity away from the burner centerline into the high temperature reaction zone, where acetylene is oxidized. Figure 5 indicates that the chemical role of acetylene changes with height above the burner. Low in the flame the destruction rate exhibits a maximum value ( $R_i = -1.0 \times 10^{19}$  molecules/(cc·sec)) near the high temperature, primary reaction zone, and the production rate feature ( $R_i = 1.5 \times 10^{19}$  molecules/(cc·sec)) occurs slightly toward the fuel side. This peak in the production rate is located on the high temperature side of the observed maximum in the concentration profile (see Fig. 3). Higher in this flame it appears that the production rate peak is diminished by a new destruction feature (see arrow in Figure 5). An additional loss mechanism for acetylene higher in the flame is consistent with the proposed importance of this intermediate hydrocarbon in particle growth chemistry. The location of this new feature coincides with the peak concentrations of very small soot particles detected in our earlier work [4].

#### CONCLUSIONS AND FUTURE DIRECTIONS:

We have made quantitative species concentration measurements and analyzed these profile data to obtain chemical rates for production and destruction of intermediate hydrocarbons in a methane/air flame. In the near future detailed kinetic models will be evaluated at specific flame locations in an attempt to verify their application to diffusion flame systems. Specifically, can the models (given as inputs measured concentrations, temperature, and mass transport) predict net chemical fluxes which agree with our measured production rates? An analysis such as this will indicate possible shortcomings in both our knowledge of the chemical structure of these systems (i.e., radical concentrations are not well known) as well as deficiencies in proposed models for chemical growth.

## SULFUR TRIOXIDE FORMATION IN HIGH SULFUR RESIDUAL OIL FLAMES

Peter M. Walsh, Walter F. Farmayan,\* Thomas Kolb,† János M. Beér

Energy Laboratory and Department of Chemical Engineering  
Massachusetts Institute of Technology  
Cambridge, MA 02139

### INTRODUCTION

Heavy residual fuel oils usually contain between 1 and 4 wt% sulfur. Although  $\text{SO}_2$  is the principal product of fuel sulfur oxidation, as much as 8 to 10 mol% of the sulfur oxides are present as  $\text{SO}_3$  in the flue gas arriving at the cold end of the convective section in an electric utility boiler. Sulfur trioxide is quantitatively converted to sulfuric acid vapor in the presence of typical flue gas water vapor concentrations at temperatures below about 500 K (Halstead and Talbot, 1980). Condensation of sulfuric acid on surfaces at temperatures below the acid dewpoint is responsible for corrosion of cold end components, especially the air preheater. The accumulation of unburned carbon particles on the wet surfaces and reentrainment of their agglomerates is the source of acid smuts (Blum, Lees and Rendle, 1959; Conolly and Kelsell, 1982). The adsorption of sulfuric acid on ash and unburned carbon may make a significant contribution to the mass of stack gas particulates.

The most severe acid deposition and sulfate emissions problems are associated with catalytic oxidation of  $\text{SO}_2$  to  $\text{SO}_3$  over vanadium-containing deposits on tubes in the convective section. However, 1 to 2 mol% of the sulfur oxides are thought to be present as  $\text{SO}_3$  in the furnace exit gas. Reidich and Reifenhäuser (1980) reported 2 mol% of the sulfur oxides as  $\text{SO}_3$  (25 mol ppm of total gas) at the furnace exit in a 300 MW, tangentially fired boiler operated at 0.6 mol% excess  $\text{O}_2$  with 2 wt% sulfur fuel. This is an amount sufficient to cause troublesome acid deposition and make a significant contribution to particulate loading, even in the absence of additional  $\text{SO}_3$  formation in the convective section. Experience has shown that  $\text{SO}_3$  formation can be controlled by reducing excess air, but this is accompanied by an increase in unburned carbon (coke cenospheres). Sulfur trioxide formation in the furnace is one component of a set of coupled processes making contributions to acid deposition and stack particulates (Cunningham and Jackson, 1978; Harada, Naito, Tsuchiya, and Nakajima, 1981).

Substantial progress has recently been made in the quantitative description of sulfur chemistry in flames (Muller, Schofield, Steinberg, and Broida, 1979; Kramlich, Malte, and Grosshandler, 1981; Smith, Wang, Tseregounis, and Westbrook, 1983; Wendt, Wootan, and Corley, 1983). Squires (1982) combined a detailed chemical kinetic description of reactions in the furnace with a global model for heterogeneous oxidation of  $\text{SO}_2$  over tube deposits in the convective section. The predictions of this model were in good agreement with observed levels of  $\text{SO}_3$  in the flue gases of 500 MW and 60 MW boilers. The present paper describes the initial steps of an investigation in which the results of fundamental kinetic studies are applied to the interpretation of direct measurements of  $\text{SO}_3$  in boiler-type turbulent diffusion flames.

## EXPERIMENTAL

The measurements were made in the 1.2 x 1.2 m combustion tunnel in the MIT Combustion Research Facility (Beér, Jacques, Farmayan, and Taylor, 1981). The fuel was a mixture of residual oils produced by the Exxon refinery at Aruba. Its analysis was (wt%): carbon 85.80, hydrogen 10.86, nitrogen 0.47, sulfur 2.15, oxygen 0.57, and ash 0.10. Asphaltenes (IP 143/57) were 10.5 wt%, and the metal contents (wt ppm) were: vanadium 421, nickel 51, iron 15, sodium 9.8, calcium 20, and magnesium 4.8. The heating value was 42.5 MJ/kg and viscosity was 213 Saybolt Furol seconds at 50°C. The fuel was heated to 389 K, fired at 0.05 kg/s (2 MW thermal), and atomized by a 70° (full angle) six-hole "Y" jet nozzle with air as the atomizing medium. Combusting air was preheated to 560 K and supplied through a 0.176 m diameter duct to a 50° (full angle) divergent quarl mounted flush with one end wall of the combustion chamber. Several parameters were varied in order to examine their effects on carbon burnout and SO<sub>3</sub> formation: atomizer position, atomizing air/fuel ratio, combustion air swirl, and excess air. Five different commercial preparations designed to promote carbon burnout were added to the fuel; these contained compounds of the metals iron, zirconium, and cerium. One run was made with fuel emulsified with 7 wt% water. The experimental conditions are given in Table 1.

Gas temperature and composition (O<sub>2</sub>, CO<sub>2</sub>, CO, SO<sub>2</sub>, NO) were determined using standard techniques. The axial component of the gas velocity was measured using a two-hole impact probe. A representative set of gas temperature, velocity, and composition profiles is shown in Fig. 1. Axial positions are measured from the exit of the 0.176 m diameter combustion air nozzle. For calculation purposes, the temperature, velocity, and carbon monoxide profiles in the region following the peak flame temperature at  $z = z_0 = 0.95$  m were fit by the following relations, shown as solid lines in Fig. 1:

$$T = T_0 - \alpha(z - z_0) \quad 1)$$

$$u = \beta/z \quad 2)$$

$$X_{CO} = X_{CO,0} \exp[-\gamma(z - z_0)] \quad 3)$$

Table 2. Data used in the calculations. The mole fractions of CO<sub>2</sub>, O<sub>2</sub>, and SO<sub>2</sub> are calculated flue gas values (wet) based on the fuel analysis and air/fuel ratio.

220	1990	133	15	.0338	1.776	.134	.00885	1250

Values of the parameters are given in Table 2. A mean gas residence time of 1 s, typical of a tightly designed oil-fired utility boiler, is reached at a distance of about 2.9 m from the combustion air nozzle.

$\text{SO}_3$  in the flame gases was determined using the Severn Science Ltd./Marchwood Engineering Laboratories (Central Electricity Generating Board, UK) continuously recording  $\text{SO}_3/\text{H}_2\text{SO}_4$  monitor (Jackson, Hilton, and Buddery, 1981). This instrument is intended primarily as a flue or stack gas monitor. The 2 m long heated sampling probe supplied with the instrument was adapted for sampling in the flame by enclosing it in a water-cooled sheath. The glass sampling tube was replaced with one made of quartz. The indicated mole fractions of  $\text{SO}_3$  along the flame axis are shown in Fig. 2.

After making a measurement, brown, orange, black, and yellow deposits were observed over 60 mm of the inside wall at the tip of the quartz sampling tube. Most of the deposit was soluble in 0.05 M  $\text{H}_2\text{SO}_4(\text{aq})$ . If this deposit contains vanadium it may catalyze the oxidation of  $\text{SO}_2$  to  $\text{SO}_3$ . Even though the composition and physical properties of the probe deposit have not been determined, the available information can be used to place some approximate limits on the change in  $\text{SO}_3$  content of the gas during sampling. Kinetic studies of related systems have been reviewed by Urbanek and Trela (1980), although most of this work has been conducted at relatively high  $\text{SO}_2$  and  $\text{O}_2$  (order of 10 mol%) and in the temperature range (650 to 850 K) over which conversion of  $\text{SO}_2$  to  $\text{SO}_3$  is greatest in flow reactors. The portion of the sampling tube coated with deposit was treated as a one-dimensional tubular reactor with catalytic wall. The wall temperature was assumed to decrease linearly from a value equal to the gas temperature at the probe tip to the melting point of  $\text{V}_2\text{O}_5$  (943 K) at the end of the deposit. The sample enters the quartz tube at high temperature and with  $\text{SO}_3$  at greater than equilibrium concentration. Conversion near the tube entrance was assumed to be controlled by boundary layer diffusion of  $\text{SO}_3$  to and from the deposit surface, where  $\text{SO}_3$  is in equilibrium with excess amounts of  $\text{SO}_2$  and  $\text{O}_2$ . The composition of the bulk gas then shifts until it is equal to the equilibrium composition at the deposit. When the entering gas is at 1625 K and contains 10 mol ppm  $\text{SO}_3$ , 1250 mol ppm  $\text{SO}_2$ , and 1 mol%  $\text{O}_2$ , this occurs at a distance of 20 mm into the probe, at which point the mole fraction of  $\text{SO}_3$  has decreased to 7 mol ppm. Production of  $\text{SO}_3$  from this point onward is assumed to be kinetically controlled, with a rate proportional to the deposit geometric surface area. The mechanism of Mars and Maessen (1968) was used with activity per unit area estimated from the total areas and effectiveness factors reported by Livbjerg and Villadsen (1972). This calculation resulted in  $\text{SO}_3$  equal to 27 mol ppm at a distance of 60 mm from the tube entrance. Therefore, in the event that the deposit has an activity comparable with that of an industrial alkali-promoted vanadium catalyst whose kinetic parameters are the same at 1400 K as at 800 K,  $\text{SO}_3$  could be altered by the sampling procedure. Inspection of the  $\text{SO}_3$  profiles shows that amounts of about 10 mol ppm were observed in 6 of the 9 runs under the conditions of the above calculation ( $z = 3$  to 4 m). This indicates that the greatest errors would have occurred if  $\text{SO}_3$  in the entering gas had actually been near equilibrium, with most of the observed  $\text{SO}_3$  produced in the probe. Based on these observations the limits of error in the measurements are tentatively estimated to be plus 100% and minus 50% of the indicated values. Further study of this problem is warranted, not only by its importance to the sampling technique, but because the situation is analogous to that encountered in the convective section of a boiler, where vanadium and alkali metal tube deposits catalyze the oxidation of  $\text{SO}_2$  as the flue gas is cooled.

#### CALCULATIONS

Notwithstanding the uncertainty in the accuracy of the  $\text{SO}_3$  measurements, it is worthwhile to compare the observations with calculations based on a simple set of assumptions. The objective is to determine if  $\text{SO}_3$  in the furnace exit gas of a

utility boiler might be correlated with flame characteristics which are known or can be estimated, such as fuel sulfur content, peak flame temperature, furnace exit gas temperature, excess air, and carbon monoxide.

A set of reactions which might account for the behavior of  $SO_3$  in the present system is (Kramlich, Malte, and Grosshandler, 1981):

The rate coefficient for Reaction 1 is given by Troe (1978); that for Reaction 2 by Smith, Wang, Tserregounis, and Westbrook (1982). The reverse of Reaction 2 has a negligible rate under the conditions of interest here. Reaction 3 is neglected in the present calculation, although Kramlich et al. provide evidence that it is important in lean hydrocarbon combustion. The concentration of third bodies, M, is taken equal to the total gas concentration, C (but see Kramlich et al., 1981). The net rate of  $SO_3$  production, apparently quite small over much of the region of the measurements, is then:

$$r_{SO_3} = k_1 C_{SO_2} C_O C - k_{-1} C_{SO_3} C - k_2 C_{SO_3} C_O \cong 0 \quad 4)$$

$$\frac{C_{SO_3}}{C_{SO_2}} = \frac{x_{SO_3}}{x_{SO_2}} \cong \frac{k_1 C_O C}{k_{-1} C + k_2 C_O} \quad 5)$$

Under the above assumptions the ratio of  $SO_3$  to  $SO_2$  is limited to the range

$$K_1 C_{O,eq} \leq \frac{x_{SO_3}}{x_{SO_2}} \leq \frac{k_1}{k_2} C \quad 6)$$

as long as the system is not frozen. The total equilibrium mole fractions of  $SO_3$ , shown as dashed lines in Fig. 2, are everywhere less than the measured values, which are, in turn, much less than the right hand side of Equation 6, especially near the furnace exit. In order to apply Equation 5 we require an estimate of the oxygen atom concentration. In discussing this same problem Merryman and Levy (1979) suggested that an estimate of the oxygen atom concentration might be obtained by assuming equilibration of the principal reactions by which they are formed during CO oxidation:

$$C_0 = \frac{K_4 C_{CO} C_{O_2}}{C_{CO_2}} \quad 7)$$

The mole fractions of  $O_2$ ,  $CO_2$ , and  $SO_2$  were taken constant and equal to the outlet values, given in Table 2. Sulfur trioxide mole fractions calculated using Equations 1, 3, 5, and 7 are shown as solid lines in Fig. 2.

The calculated profiles satisfactorily reproduce the magnitude of the  $SO_3$  measurements near a mean residence time of 1 s ( $z = 2.9$  m) in most of the lower excess  $O_2$  (1 mol%) cases. Large discrepancies are observed in two instances (Runs 212 and 213); these are distinguished by low temperature (212), high levels of  $CO$  (213), and high excess  $O_2$  (both). The calculated values are especially sensitive to temperature. Most important is the fact that the calculation predicts  $SO_3$  increasing with distance near the furnace outlet, while most of the measurements show a tendency of  $SO_3$  to approach equilibrium. The assumption of equilibration of Reaction 4 was not originally intended by Merryman and Levy (1979) to be applied at points so far into the postflame region, but at shorter times. As the rate of  $CO$  oxidation slows, due to  $CO$  consumption and decreasing temperature, Equation 7 becomes a progressively poorer approximation. The  $CO$  mole fractions at  $z = 3.1$  m are in the range 320 to 950 ppm, no longer sufficient to maintain significant super-equilibrium concentration of oxygen atoms against competition with recombination, for example, by Reactions 1 and 2 themselves. Because the calculation is least reliable near the furnace exit, it would be unwise to use this approximation to estimate  $SO_3$  in furnace exit gas. The steady state approach (Equation 5) might still be useful however, if the decay of oxygen atoms at long times can be related to  $CO$  and stable species concentrations.

#### SUMMARY

Mole fractions of sulfur trioxide were measured along the axis of a confined turbulent diffusion flame, under conditions simulating those in electric utility boilers. The fuel was a No. 6 residual oil containing 2.2 wt% sulfur, fired at the rate of 0.05 kg/s or 2 MW(thermal). The sulfur trioxide mole fractions were in the range from 3 to 25 mol ppm; representing 0.2 to 2% of the total sulfur. An estimate was made of the contribution of catalytic  $SO_3$  formation by ash constituents deposited in the probe. The uncertainty introduced from this source was estimated to be plus 100% and minus 50% of the indicated value. The observed mole fractions were approximately steady and everywhere greater than the local total equilibrium values. Sulfur trioxide mole fractions were calculated by assuming that the steady state is determined by atomic oxygen reactions, with atomic oxygen in partial equilibrium with carbon monoxide, carbon dioxide, and molecular oxygen. The results of this calculation approximately reproduced the experimental measurements under most, but not all, sets of conditions investigated. Because of its sensitivity to temperature, carbon monoxide, and oxygen this approximation is not recommended for the estimation of  $SO_3$  in furnace exit gases.

#### ACKNOWLEDGEMENTS

We thank Bonnie Caputo of the MIT Energy Laboratory for the layout and typing of the drafts and final manuscript. This work is supported by Babcock and Wilcox Canada, Canadian Electrical Association, Electric Power Research Institute, Empire State Electric Energy Research Corp., Florida Power and Light Co., Northeast Utilities Service Co., and Shell Development Co.

## NOMENCLATURE

C	total gas concentration, kmol/m <sup>3</sup>
C <sub>i</sub>	concentration of gaseous species i, kmol/m <sup>3</sup>
k <sub>j</sub>	rate coefficient of Reaction j in forward direction, various units
k <sub>-j</sub>	rate coefficient of Reaction j in reverse direction, various units
K <sub>j</sub>	equilibrium constant for reaction j, = k <sub>j</sub> /k <sub>-j</sub>
r <sub>i</sub>	net rate of production of species i by chemical reaction, kmol/m <sup>3</sup> s
Sw	combustion air Swirl Number
T	temperature, K
u	axial component of gas velocity, m/s
X <sub>i</sub>	mole fraction of species i
z	axial distance from the combustion air nozzle, m
α	mean temperature gradient along the flame axis, Equation 1, K/m
B	gas velocity decay constant, Equation 2, m <sup>2</sup> /s
γ	carbon monoxide decay constant, Equation 3, m <sup>-1</sup>

## Subscripts

o	evaluated at z = z <sub>o</sub> = 0.95 m from the combustion air nozzle

## RAMAN STUDIES OF HALON FIRE RETARDANTS.

J. H. May, F. S. Allen, M. R. Ondrias, R. E. Tapscott,  
H. D. Beeson, and D. M. Zallen.

Raman spectroscopy can be used as a passive probe for the study of active systems. Various types of analytical determinations can be made with-out perturbing the system under study. Of interest is the elucidation of the extinction processes employed by Halon type extinguishing agents. Raman has in the past been used to study molecules such as  $H_2O$ ,  $N_2$ , and  $CO_2$  in flames (1). Halons and pyrolyzed products, having vibrations that are more polarization sensitive than the above molecules, should then be readily analyzed in flames. As an initial approach to this problem we are studying the pyrolysis of Halon 2402 (1,2 dibromotetrafluoroethane). The pyrolysis products are isolated using vacuum line techniques, and identified using GC/MS and Raman. A library of the Raman spectra from each component is being formed for subsequent use in flame analysis.

Experimentally, we use a tube furnace with a specially designed tube, having detachable nitrogen traps on each end, and also capable of holding a vacuum. To simulate the combustion process, Halon 2402 is frozen in one of the nitrogen traps, and the whole system is brought to high vacuum. The Halon is then allowed to vacuum transfer through the pyrolysis tube, which is at approximately  $790^\circ C$ , to the other nitrogen trap. This process is repeated several times. The products are then vacuum distilled, capturing fractions as they come over, in different, sealable cuvettes. Presently all fractions are studied in the gas phase at room temperature.

The Raman data are collected on an instrument made up of:

1) An EG&G Princeton Applied Research model 1420 intensified silicon photodiode array tube coupled with its model 1218 solid state detector controller, and the model 1215 computer console.

2) A SPEX model 1877 triplemate monochromater.

3) A Coherent model CR-4 Argon ion laser, capable of producing over 3 watts of continuous wave power at the 488.0 nm. line.

Spectra, in the range of  $100\text{ cm}^{-1}$  to  $1000\text{ cm}^{-1}$  can be obtained at a single setting of the monochromater. Since Raman spectra of many of the thermal degradation products are not available, we have used a Finnigan, series 4900, GC/MS to identify the products that are obtained from the pyrolysis experiment. Raman spectra collected on these components will subsequently form a spectral library of the pyrolysis products.

Figures 1. and 2. are the Raman spectra of the first fraction collected from the vacuum distillation process on the pyrolyzed 2402. The complexity of the spectra suggests that more than one component is present. The GC/MS revealed that the gas contained only tetrafluoroethylene, and bromotrifluoromethane (Halon 1301) in significant concentrations. Figures 3. and 4. are the Raman spectra of pure 1301, and it is evident that its spectral bands match many of the bands in the distilled fraction.

Pure tetrafluoroethylene will be examined to identify its spectral contribution to pyrolysis products spectra. The vacuum distillation was done at 500 millitorr, later distillations using higher pressures should provide better separation of the fractions.

Each of these spectra took thirty minutes to collect, fifteen minutes for the signal spectra, and another fifteen for the background ( Raman spectra normally require the subtraction of the background spectra, taken with the excitation source off, from the signal spectra. This is especially true for photodiode array detectors.). Accurate spectra, to within 2  $\text{cm}^{-1}$ , of all but the weaker bands can be taken in a minute or less if desired ( This includes background spectra.). Using pulsed, or higher intensity C.W. lasers, spectra could be taken in less time with even better signal to noise ratios.

As a result of these preliminary studies, we will build a library of Raman spectra for the stable products produced by the simulated combustion of the Halon 2402 in a vacuum, as well as in oxidizing and reducing environments. This library will then be used in subsequent studies to identify which of the products are present in flames near extinction due to the presence of Halon 2402.
